Contents

Preface	ix
Editorial Board and Contributing Authors	xi
PART ONE: INTRODUCTION AND OVERVIEW	
Characteristics of the Industrial Minerals Sector	3
Classification of Industrial Minerals and Rocks	7
World Distribution of Industrial Minerals Deposits	13
International Trade in Industrial Minerals	49
Applying Industrial Marketing Concepts to Industrial Minerals	61
Due Diligence and Financial Valuation of Industrial Mineral Assets	67
Rail Transportation of Industrial Minerals	79
Road Transportation of Industrial Minerals	95
Ship and Barge Transportation of Industrial Minerals	99
Mine Safety and Health Law	109
Environmental Law for Industrial Minerals and Rocks	121
Sustainable Development and Industrial Minerals	133
PART TWO: COMMODITIES	
Abrasives	145
Aggregates	
Construction Sand and Gravel	159
Crushed Stone	171
Lightweight Aggregates	181
Asbestos	195
Barium Minerals	219
Bauxite	227
Beryllium Minerals	263
Boron and Borates	275
Bromine	285
Chemicals	295
Chromite	309
Clays	
An Overview	335
Ball Clays	343
Bentonite	357
Common Clays and Shale	369
Fuller's Earth	373
Kaolin	383
Palygorskite and Sepiolite (Hormites)	401
Refractory Clays	407

Diamonds	415
Diatomite	433
Feldspars	451
Fluorspar	461
Garnet	475
Gilsonite	481
Glaucinite	495
Graphite	507
Gypsum and Anhydrite	519
Iodine	541
Kyanite, Andalusite, Sillimanite, and Mullite	553
Lime	561
Limestone and Dolomite	581
Lithium Resources	599
Magnesium Minerals and Compounds	615
Manganese	631
Mica	637
Nepheline Syenite	653
Nitrogen and Nitrates	671
Olivine	679
Perlite	685
Phosphate Rock	703
Potash	723
Pumice, Pumicite, and Volcanic Cinder	743
Pyrophyllite	755
Rare Earth Elements	769
Salt	793
Silica	
Industrial Sand and Sandstone	815
High Pure and Ultra-High Pure Quartz	833
Specialty Silica Materials	839
Soda Ash	859
Sodium Sulfate Resources	879
Stone	
Decorative Stone	893
Dimension Stone	907
Strontium Minerals	925
Sulfur	935
Talc	971
Titanium	987
Tripoli (Microcrystalline Silica)	1005
Vermiculite	1015
Wollastonite	1027
Zeolites	1039
Zirconium and Hafnium	1065

PART THREE: MARKETS AND USES

Absorbents and Desiccants	1075
Minerals Used in Formulating and Manufacturing Catalysts	1087
Construction Uses	
Adobe and Earthen Construction	1095
Aggregates	1105

Cement and Cement Raw Materials	1121
Flooring Materials	1137
Gypsum Plasters and Wallboards	1143
Insulation	1153
Pozzolans and Supplementary Cementitious Materials	1161
Roofing Materials	1173
Structural Clay Products	1179
Cosmetics	1185
Electronic and Optical Materials	1193
Environmental Uses	
Acid Neutralization	1205
Asbestos Substitutes	1215
Clay Liners and Barriers	1229
Flue Gas Desulfurization	1251
Water and Sewage Treatment	1259
Fertilizers	1269
Filler and Extender Uses	
Adhesives, Caulks, and Sealants	1281
Filler and Coating Pigments for Papermakers	1287
Paint and Coatings	1301
Plastics	1321
Rubber	1327
Filters and Process Aids	1337
Fine Ceramic Products	1353
Glass	
Container Glass	1365
Fiberglass	1369
Flat Glass	1379
Specialty Glass	1383
Metallurgical Uses	
Agglomeration Processes—Pelletizing and Sintering	1391
Fluxes for Metallurgy	1405
Fluxes Used in Fusion Welding and Brazing	1423
Foundry Sands	1433
Nanomaterials	1441
Pigments	1453
Refractories	1471
Soil Amendments	1477
Well Drilling Materials	1487
Appendix A: Resource and Reserve Classification	1497
Appendix B: Sieve Chart	1499
Appendix C: Conversion Chart	1501
Index	1507

Dedication

*With deep admiration for his countless contributions to the field of industrial minerals,
we dedicate this 7th edition of Industrial Minerals and Rocks to the memory of
our friend and colleague, Albert Francis Alsobrook, 1942–2004.*

*Frank was an industrial minerals geologist who was widely respected by his peers
and admired by his colleagues throughout an illustrious career that spanned 35 years.
He was a Distinguished Member of SME and received the Hal Williams Hardinge Award
in 2003. He served with us as a senior editor in the early stages of the
multiyear effort to publish this 7th edition.*

*As the inspirational force behind this endeavor,
Frank is truly most deserving
of this dedication.*

Preface

The vision for the 7th edition of *Industrial Minerals and Rocks* is to build on the strengths of the previous editions while adding significant new content to ensure utility and relevance to readers for years to come. The success of previous editions made this book a widely read global reference that serves as one of the most authoritative single sources for timely information on industrial minerals, their uses, and the markets where they find myriad applications.

We recognize that since the publication of the 6th edition in 1994, changes in the global economy have had a significant impact on mining, processing, and marketing industrial minerals. The challenge for this edition, then, was to capture the substantial and wide-ranging changes and their complex ramifications for the industry. For example, numerous mergers and acquisitions within the minerals and mining industries, consolidations among consuming industries, and the emergence of China and India as major players in industrial minerals markets have altered the landscape in which the industry operates. At the same time, development of new technologies and globalization of the customer base have driven fast-paced innovation in processing, packaging, transportation, and end use.

Growing emphasis on sustainable development and increasing concerns for the environment and health and safety have also affected the industry in many ways. In one positive example, we now have a common platform for advancing environmental stewardship and a universal goal to use mineral resources wisely. Rapidly rising energy costs will also shape the future of industrial minerals. Higher fuel prices affect mining, processing, and transportation, and push the industry to discover innovative ways to reduce energy consumption and to process minerals more efficiently. Increasingly, industrial minerals are an integral part of the solution to rising energy costs because they serve as raw materials for products such as solar panels designed to conserve or generate energy.

As in previous editions, we divided the book into three parts. The first part contains standalone introductory chapters focusing on topics relevant to the industry as a whole: industrial minerals transportation, marketing, sustainable development, health and safety, and mining and environmental law. Chapters covering more than 60 individual industrial minerals, rocks, and materials make up the second part. Where appropriate, a few chapters in this part include updated statistics, but otherwise retain most of the content from the previous edition. In the third part, readers can find information organized by market or end use. Here, information is presented on industrial minerals used in various applications such as construction and metallurgy, among many others. The 7th edition also offers appendixes containing frequently referenced information as well as a comprehensive index.

To ensure the publication of a complete and accurate reference that readers can depend on for many years, an international group of volunteer authors, coauthors, and associate editors—all recognized experts and leaders in their fields—was assembled. Drawing on experts from around the world has given the 7th edition a more global perspective than previous editions. Next, an exhaustive review process was implemented that included five stages of content and technical editing and at least one peer review. Finally, an outstanding group of professional copy editors, proofreaders, graphic designers, and indexers worked to bring clarity, readability, and visual appeal to *Industrial Minerals and Rocks*.

In Appreciation

The authors, editors, and publisher of *Industrial Minerals and Rocks: Commodities, Markets, and Uses* express appreciation to the Robert M. Dreyer Fund and AIME's Seeley W. Mudd Memorial Fund for support in the publication of this 7th edition.

Robert M. Dreyer Fund

Proceeds from the trust established by the late Robert M. Dreyer are used to fund the Dreyer Award, to recognize outstanding achievement in applied economic geology, and to support the professional development of geologists in the field of nonmetalliferous geology. Robert Dreyer received his BS degree from Northwestern University, and an MS and Ph.D. in geology and geophysics from the California Institute of Technology. Dreyer's professional career was extensive in scope: he was employed as minerals manager for Associated Oil and Gas Co., served as assistant chief geologist for Reynolds Metals Co., and was employed as chief geologist for Kerr-McGee Oil Corp. and for Kaiser Aluminum Co. Additionally, Dr. Dreyer was a professor and department chair for the University of Kansas and served as president of Western Mineral Associates. Dreyer retired in 1984. Dr. Dreyer was a former chair of the SME Industrial Minerals Division and an SME board member.

Seeley W. Mudd Memorial Fund

The Seeley W. Mudd Memorial Fund was entrusted to AIME by his family in 1929. Proceeds from the fund are intended to perpetuate Mudd's lifelong interest in the mining industry. Mudd graduated from Washington University in St. Louis, Missouri, in 1883, and served as a colonel during World War I. Seeley W. Mudd gained lasting recognition in the mining profession for the discovery and development of extensive mineral deposits. He is still widely known for his contributions to the growth of mining enterprises such as Ray Consolidated Copper Co., Texas Gulf Sulphur Co., and Cyprus Mining Corp. Colonel Mudd was a member of AIME for 43 years and during that time served as vice president and director.

PART ONE

Introduction and Overview

Characteristics of the Industrial Minerals Sector

Kip Jeffrey

INTRODUCTION

If DNA is the building block of life, then industrial minerals and rocks are literally the building blocks of our way of life. Industrial minerals and rocks are an exceptionally diverse and vital group of raw materials that underpin almost all aspects of human activity, infrastructure, and standard of living. More than 60 commodities are commonly considered industrial minerals and rocks, and they provide myriad products used by every conceivable industry. Although industrial minerals permeate every aspect of daily life, their presence and their role are often invisible.

In certain respects, the production of industrial minerals and rocks constitutes one of the most intimate and familiar of industries because few domestic or industrial products do not contain industrial minerals and rocks or require them at some point in their manufacture. To use a popular slogan, “If it’s not grown, it’s mined.” This applies to all mining but particularly to the larger and more diverse industrial minerals and rocks sector. Add to this that most crops could not be grown, harvested, or transported to market without industrial minerals-based fertilizers, equipment, and infrastructure, and the all-pervading presence of industrial minerals and rocks comes into sharper focus.

DEFINITION

The precise definition of industrial minerals and rocks is far from straightforward. However, a widely used definition is “any rock, mineral, or other naturally occurring substance of economic value, exclusive of metal ores, mineral fuels, and gemstones: one of the non-metallics” (Bates 1975, p. 3).

This definition includes the hugely important construction materials sector as well as specialized industrial minerals, but complex interactions between consuming industries produce a number of apparent anomalies (and, as such, would not be regarded as falling under this definition). Bauxite, for example, is the main ore of aluminum, but it is also used to manufacture alumina and other aluminum compounds that have applications in the refractories, abrasives, and fillers markets. Titanium metal is produced from the mineral rutile, but the bulk of this mineral is mined to produce titanium dioxide (TiO_2), one of the most important white pigments. Similarly, sulfur is still widely produced from the metallic mineral pyrite (iron disulfide) produced as the by-product of copper-lead-zinc mining in volcanic massive sulfide deposits. Such deposits containing metallic minerals are therefore also important nonmetallic industrial minerals sources.

The position of gemstones is much debated, but they are included in this book because of their importance as high-value minerals. Diamonds and garnets, for example, are not just gems but also important industrial abrasives, and beryl can be both an ore of beryllium and the gemstone emerald or aquamarine. In many respects, gemstones are the ultimate industrial minerals, exhibiting the highest quality, perfect crystal form, and which, with minimal processing, can command the extremes of value. Most fall firmly in the nonmetallics camp.

Waste products of several bulk industrial processes are also included, because they are important industrial raw materials in their own right. Pulverized fuel ash from power stations may not be a natural raw material, but it is an important pozzolan used in the cement or construction industry. Sulfur is now dominantly extracted as a by-product of cleaning natural gas, one of the world’s major mineral fuels. On reflection, perhaps oils used for lubricants or petrochemicals should be considered industrial minerals and rocks under the preceding definition.

Industrial minerals and rocks are used in the manufacture of many products, from ceramics to plastics and refractories to paper. This book could never encompass all the downstream industries. The mining and extraction of ceramic clays, for example, is sensibly within this edition of *Industrial Minerals and Rocks*, whereas the firing of ceramics is not (Bates 1994). Even this has its exceptions, because the manufacture of cement is typically included. Equally, at a brine chlorine or rare earth processing plant, it is difficult to define when the raw materials cease to be an industrial mineral or rock and become an industrial chemical.

Clearly defining the exact extent of this industrial sector is difficult, and it is frequently easier to highlight the differences among the commodities than what they have in common. Lines must be drawn, and the contents of this book represent a consensus of many professionals in the field as to what defines the scope of industrial minerals and rocks. Nevertheless, the debate will continue, particularly as new applications and markets develop. An account of the attempts to produce classification systems for industrial minerals and rocks is given in the chapter on the classification of industrial minerals and rocks.

HISTORY

The history of industrial minerals and rocks can quite literally be traced back to the Stone Age; indeed, it defines the development of humankind through time (Kuzvart 1984). Perhaps the scale of use

was preindustrial, but the materials and technical requirements at that time were not dissimilar to some present-day natural stone and abrasives industries. The total amount and diversity of industrial minerals and construction materials used by a society are always closely linked to, and a measure of, its overall economic strength (Noetstaller 1988). Some minerals are used more as an industrial society develops, whereas others are more characteristic of postindustrial, service-dominated economies. As a country develops, however, the per capita use of minerals inevitably increases. Dominance of industrial minerals and rocks production over metal minerals production has been a measurement of economic development and a defining characteristic of a developed country (Bristow 1987). Given a still-rising world population, dominantly with in developing countries, which have a justified aspiration to higher standards of living, the future demand for industrial minerals is certain to increase.

SCOPE

The industrial minerals and rocks sector operates worldwide, and no nation on earth does not in some way use the natural raw materials at its disposal. The motivation for and magnitude of this resource utilization, however, varies widely from local subsistence activity to global-scale trade. Unlike other types of manufacturing, minerals can be worked only where they are found. Mineral resources are also a “wasting asset,” so eventually an individual deposit becomes depleted and new ones must be found or the business will close. Mines and quarries will therefore always open and close, and new deposits will constantly be sought.

Natural geological endowment dictates that some countries or regions have certain minerals they need but not others, and linked to the varying requirements for industrial raw materials, this sets up a driver for both interregional flow and international trade in industrial minerals. On a more local scale, villages, towns, and cities all need these important products, so an infrastructure of companies develops to work, distribute, and upgrade the mined materials to products that are in demand. Industrial minerals key in to the manufacturing base of each area, promoting the development of downstream industries where commodities are abundant. They drive development of road, rail, and other infrastructure to allow their extraction and transport to market, and to facilitate their import if there are not indigenous supplies. Industrial growth is almost impossible without them (Noetstaller 1988). As new uses for minerals develop or markets disappear, the demand for specific minerals fluctuates.

The range and diversity of materials are enormous, and this can be illustrated by describing two end members. Aggregates are the classic low-value, high-bulk material and are the largest sector by volume produced. Strength and other physical properties are important, but their value is largely in the inability to reduce the need for expensive components such as cement or bitumen in construction materials. The main asset is that they occupy space. They have significant “place value”; that is, the location of the deposit is vitally important because the cost of transportation is a large proportion of the delivered price (Bates 1969). Deposits near markets have major cost advantages, and most extraction sites are close to the urban centers they supply. Although often assumed to be common to the point of ubiquity, industrial minerals and rocks still need to meet strict standards or specifications, and the amount of unsuitable material always massively outweighs those deposits that can be used. For higher quality products, the specifications become tighter and the proportion of available material that can be used rapidly decreases.

At the other end of the spectrum are the high-value, low-bulk materials such as gemstones, iodine, bromine, and rare-earth elements. In a large diamond mine, for example, 50 percent of the annual revenue could be generated from only half a dozen individual large stones easily held in one hand. Deposit location is less critical and product quality will often be significantly improved by complex processing. Low-cost rocks such as aggregates and brick clays may be economically sold over only a 30- to 60-km radius, whereas borates and phosphates, for example, are truly globally traded. Between these two extremes are the majority of industrial minerals and rocks commodities such as kaolin and salt that service local, national, and international industries.

The industrial minerals and rocks sector embraces scales of activity from artisanal mining of gems through family-operated gravel or building stone quarries (so-called Ma and Pa operations) and limestone quarries supplying construction materials to a large region, and ultimately to some of the world's largest mining and processing plants. Most industrial minerals operations, however, are small- to medium-sized and play a major role in local economic development.

Because good transport infrastructure is required, and transshipment of minerals is costly, deposits located near existing ports, railways, waterways, and major roads are the most important. In many larger, low-population countries, plans showing the distribution of industrial minerals deposits often mirror the road and rail networks. In other words, only deposits that have the potential to be easily accessed have been identified; the rest of the deposits await expansion of transport networks before they are sought in earnest. Even more than metal resources, a new road or railway can transform the economics of an industrial minerals deposit, making it feasible.

PRODUCTS AND SPECIFICATIONS

Many industrial minerals are used in an essentially raw form whereby much of their intrinsic characteristics remain. Specific companies, deposits, and even sections of a deposit therefore supply materials of varying qualities, and these may also change over time. Quality and competitive advantage are therefore crucial issues imbued by the deposit itself. This is again completely unlike the metals industry, where copper metal from Chile is little different from copper from Zambia or the United States.

Industries using industrial minerals and rocks generally demand tight specifications based on a wide range of physical and chemical criteria, often unique to particular applications or products (Harben and Bates 1984); the clump factor for bentonite used in pet litters is one that immediately comes to mind. These specifications have tended to become more stringent over time as more advanced manufacturing methods have lower tolerance of raw material variation.

As a consequence, mineral processing has increased considerably to meet these specifications, and the full range of mineral separation methods used in metals and other mining industries is now deployed (Harben and Bates 1990). Almost all operations working solid minerals involve excavation, comminution, sizing, and packaging. To ensure high-purity products, other plants rely on using flotation, density, magnetic, chemical, electrostatic, and other techniques to remove potentially deleterious components. A vast array of commodity-specific techniques has also been developed to optimize product quality and performance. Some industrial minerals and rocks are processed to highly refined forms, even to their elemental chemical components.

Even today, inexpensive, low-technology methods that will still meet stringent quality requirements are needed for many

internationally traded industrial mineral commodities. In Turkey and the Middle East, hand-sorting of K-feldspar is essential to produce the high-quality products used in the European ceramics and glass industries. In China, magnesite, mica, and several other commodities are hand-sorted and exported worldwide. By contrast, industrial minerals products are becoming increasingly sophisticated, and kaolin used in paper manufacture is typically tightly sized at the sub-micron level, and then chemically brightened, delaminated, and rheologically modified. Carbonate fillers for the plastics industry have their naturally hydrophilic calcite surfaces modified so that they are more easily wetted by organic-based formulations. Minerals are increasingly at the cutting edge of materials science.

Because of their generally low value, most industrial minerals and rocks are worked from open-pit operations. Depending on scale and location, the degree of mechanization varies from a multimillion-ton surface mine using large excavators to a hand-dug pit with product transportation by wheelbarrow. Only for higher-value commodities, or when essential cheaper commodities are in extremely short supply, can underground mining usually be justified. There is, however, a trend toward more underground extraction due to perceived environmental benefits and a market for low-cost products such as aggregates and limestone, which are now worked this way in some countries.

Although deposits are generally exploited for single minerals, a significant number are worked together as coproducts, such as fluorite and barite from Mississippi Valley-type lead-zinc deposits, or quartz, feldspar, and mica from pegmatites. In even more cases, by-products such as dimension stone are recovered during aggregate production. This makes the supply-and-demand relationship of these minerals complex because fluctuations in the market for the dominant product will dictate supply of by-product minerals independent of their own demand.

Most industrial minerals and rocks commodities also have multiple uses. For instance, a pure limestone deposit could supply material for lime, aggregate, and cement production, in granular form for flue-gas desulfurization, and in a range of powders for fillers, soil stabilization, and agricultural use. Each of these can command very different prices per ton, so assessing the overall value of the deposit is difficult and involves assessing for multiple quality requirements and variable product splits. In many cases, the evaluation process for an industrial minerals resource is considerably more technically complex than that for metal deposits.

ECONOMICS

Metals and petroleum are largely sold through international exchanges, whereas industrial minerals and rocks producers have to compete directly with each other to gain contracts and develop relationships with customers. Competition between companies is frequently ferocious. It is ultimately the same supply-and-demand market approach of other manufacturing industries but with very different constraints. Without a market for the products, a mineral is effectively worthless. Exploration for new industrial minerals deposits is often initiated because a new niche or emerging market has been identified (Coope 1982; Bristow 1987).

Prices for industrial minerals and rocks generally exhibit greater stability than prices for the more cyclic metals and oil. The growth in the use of most industrial minerals has been accompanied by a decrease or plateau in prices because competition is so intense. It is now technically possible to work at larger scales with consequently lower production costs. More important, over the last 10 to 20 years, the development of exporting capacity from Eastern Europe and especially China, with its massive resources and aggressive pricing policies, has led to cutthroat pricing in the rest

of the world in an attempt to compete. This has ultimately led to import quotas and tariffs being applied to some Chinese products to protect other international sources.

Globalization is an important economic driver in the world industrial minerals sector. Large international corporations such as Imerys of France and Sibelco of Belgium have formed by consolidation and acquisition of smaller companies. This process has led, in some cases, to one or two corporations having dominant control over individual mineral commodities such as diamonds, borates, nepheline syenite, garnet, and talc.

Some parts of the industry simply produce the raw minerals and sell these products to consuming industries, whereas others are more vertically integrated to process a range of intermediate or end-user products. Minerals-producing companies rarely provide minerals to suppliers without a raft of technical support, often involving in-house R&D facilities. To sell their products, larger mineral companies frequently undertake specific or comparative testing for a potential customer to evaluate the impact of changing materials. This often feeds through to improved (tailored or bespoke) products that fit the needs of individual users. This "partnership" approach to industrial minerals supplies is a gain different from that of other mining sectors.

SYNTHETICS AND SUBSTITUTION

As the technical demands on specific minerals increase or supplies are restricted, companies explore the possibilities of making synthetic mineral products. This is especially true for gemstones, but major industries are making synthetic zeolites for use in washing powders, as intermediates such as synthetic rutile for TiO₂ manufacture and in pigments, and in bulk materials such as magnesite, gypsum, and soda ash. In some applications, the boundaries with materials science become blurred, such as in industries making synthetic corundum and silica for laser, military, and electronics applications. Here the mineral structure has been perfected to a point not found in nature. Some of these synthetic minerals are also produced as by-products of upgrading other mineral products, but all affect the demand for primary industrial minerals from new or existing deposits.

More often, a shortage of suitable minerals supplies, or the possibility of cost savings, leads to substitution by function. Other minerals that can perform the same role in a product are then used instead. The increased use of fine-ground or precipitated calcium carbonate at the expense of kaolin in paper coating is a good example. Natural stone businesses also have to consider cultural and architectural trends, whereas colored gemstone demand is controlled by whims and cycles of fashion, which can change rapidly and in ways that are hard to predict.

So in the industrial minerals and rocks supply game, minerals producers must not only strive to supply the best product they can but also must keep an eye on their own market, their customers' markets, and overall product cost structure if they do not wish to be "substituted."

ENVIRONMENTAL CHALLENGES AND CONTRIBUTIONS

Environmental challenges and regulation are an ever-increasing issue that now frequently dictates where deposits can be explored for and developed. This can distort the market. In many countries, it seems less important where the deposits are as opposed to where permission may be obtained for a deposit to be worked. With that said, the industry does "borrow" the land on which the deposits are located, sometimes for considerable periods of time while minerals are worked, and therefore has an important obligation to do this in a sensitive and responsible manner.

Sustainable development and what that means for the industrial minerals sector is still a major area of debate. On a local scale, some deposits will be exhausted, but how does this square with a sustainable mineral supply and environment? Clearly, today's needs for industrial raw materials must be balanced with the needs of future generations to obtain the materials they require (WCE D 1987). Despite depletion of deposits, future industrial minerals professionals will, of course, have improved technology and knowledge in exploration, development, and remediation to guide them, but the environmental consequences of resource use must not be allowed to prejudice the environment that the next generation inherits. This certainly does not mean that natural resources should not be mined and used. The fact that commodity prices are at such low levels strongly indicates that there is no impending shortage of any major industrial minerals and rocks commodity. Although new sources can currently be found apace with consumption rates, this might not always be the case.

Despite centuries of mineral exploitation, only one industrial mineral has actually "run out" (in commercially extractable terms): cryolite, a rare fluoride mineral used in smelting aluminum (and there may well be commercial deposits yet to be found). Cryolite is now made synthetically. Market- and technology-driven substitution has actively prevented exhaustion of individual commodities, and the ability to replace reserves continues to outstrip demand. Because industrial minerals resource depletion is not imminent, the major challenge for the future is the increasing environmental cost of sustaining a growing industrial minerals and rocks supply. Full life-cycle impact analysis, particularly examining the environmental fate of industrial minerals in the consuming industries, is a growing practice.

The industrial minerals and rocks sector actually produces many minerals that are widely used in environmental protection and cleanup, such as bentonite landfill seals, limestone for flue-gas desulfurization, zeolite molecular sieves, and garnet and lime for water treatment. Some notorious enforced reductions in mineral use also occurred in this sector when the health concerns on asbestos emerged, and fluorspar production saw significant reductions in growth when chloro fluorocarbons were removed from many aerosols because of their ozone depletion potential.

Because of their relatively low value and the consequent need for low transport costs, "near market" deposits are required. In practice, this means that many deposits are close to residential centers, and, over time, buildings encroach on and even surround extraction sites. This leads to increasing problems of competition for land use and the environmental impact; the industry continues to make major efforts to be a "good neighbor."

FUTURE TRENDS

Both costs and environmental pressures will ensure more recycling of end products. This will have significant impact on some commodities, but less so than on metals. Higher world population and rising standards of living in the developing countries will drive up demand. Growth rates in China and increasingly in India, Russia, and the Far East have driven markets. Multinational companies will

make greater investment in these areas, and signs are that China will increasingly become a net importer of some of the minerals it formerly aggressively exported.

In recent years, some minerals have gained greater importance, such as the rare earth elements in electronics and mobile phones, and others may fade away because of market changes or environmental problems. No one can predict which will be the growth minerals of this century as new products and markets develop and new raw material challenges are set. Growth of Internet marketing will give global access to small-scale producers capable of supply niche markets.

More waste products, however, will find uses. In the United Kingdom, steel slag and pulverized fly ash are wastes used widely in the construction and cement industries that are, at least in some locations, in short supply. In these cases, the primary products are being made in a way that improves the qualities of the wastes or, more accurately, coproducts.

More "smart" materials technically modified for more efficient use in each application will be developed. Tailoring products using microstructural and surface modification will be more commonplace. Hybrid waste-mineral mixtures will increasingly be exploited and new processing methods, such as microwave-assisted firing, will be perfected to improve energy efficiency.

Whatever the future of the sector, the diversity of industrial minerals and rocks presents a significant challenge for professionals, consumers, educators, and other interested practitioners. It is hoped that the distillation of knowledge and experience presented by the many authors in this book will serve as a useful reference for anyone wishing to learn more about these fascinating industries.

Classification of Industrial Minerals and Rocks

Kip Jeffrey

INTRODUCTION

In the chapter on characteristics of the industrial minerals sector, a broad definition of industrial minerals and rocks is discussed—a definition that must embrace solids, liquids, gases, minerals, rocks, gems, glasses, wastes, and some manufactured products—each category with its own range of uses. Clearly, industrial minerals and rocks do their utmost to defy simple definition and are linked as closely by their differences as by their similarities.

To bring some order to this disparate field, a classification system is needed to highlight the commonalities and contrasts in a structured way. Any robust classification must address the needs of a wide range of potential users that may include (but is not limited to) academics, industrial geologists, industrial raw material users, specifiers, product formulators, technologists, engineers, managers, and financiers and investors. Given their different priorities, focus of attention, and backgrounds, it is not surprising that no single approach is universally adopted.

CLASSIFICATION SCHEMES

A range of classifications based on a variety of commodity criteria has been used over the past 50 years or more as tools for understanding the geological context, market uses, defining properties, economic contribution, and statistical significance of industrial minerals and rocks. Each approach has its strengths and weaknesses, and any durable scheme in such a dynamic industrial sector will inevitably present only part of the picture. Bates (1975) examined a number of these schemes, and more extensive comparisons have been undertaken by Kuzvart (1984), Noetstaller (1988), and Smith (1999). All of these were drawn on extensively for this review.

Berzelian

The world of systematic mineralogy has a number of classification systems that have also been applied to industrial minerals. Most museum mineral collections are catalogued by the Berzelian classification system, which is based on elements, ions, ionic groups, and compounds such as halides, oxides, carbonates, and silicates, among others. This system was used in early accounts of the non-metallics (such as in Merrill 1904) and also hydrocarbons, but not industrial rocks other than some siliceous and calcareous examples under silica and calcium carbonate, respectively. The classification did not cover waste materials, brines, or most manufactured prod-

ucts because many of these were yet to be recognized as important raw materials or products.

Alphabetic

The simplest approach, and certainly the most intuitive and accessible for those from outside the subject seeking commodity-specific information, is nothing more complex than the alphabetical listing of commodities. This has been adopted for systematic commodity reviews in earlier editions of this book (e.g., Lefond 1975; Carr 1994). Indeed, as noted by Harben and Bates (1984), the “alphabetic treatment neatly sidesteps the vexatious matter of classification.”

This edition in part adopts the same approach as it lends itself to simple encyclopedic interrogation once a mineral or commodity is identified. Approximately 60 commodities are typically included in such a listing, but these are always under review. This simplistic compositional approach works reasonably well for industrial minerals but requires a degree of clarification and consistency because subdivisions are often necessary. For example, clays can be divided into bentonites, which can in turn be divided into sodium or calcium smectites. Nomenclature for industrial rocks and other raw materials can also be variable; for example, brick clay, common clay, structural clay, and heavy clay are all common pseudonyms and are based more on application than composition.

Unfortunately, the alphabetic approach to classification obscures many important links between commodities, including similar properties they possess, geological processes that led to their formation, or applications in which they are used. For this reason, the alphabetic classification employed in this edition is supplemented by important reviews of major markets and uses for industrial minerals and rocks. Although this approach may suit those using a book format, other forms of classification have been developed that may be more useful for the consumer or the geologist.

Geological Processes

From the geologist’s perspective, there is much to be gained by trying to place a genetic classification on such a wide variety of materials (Bates 1960; Harben and Bates 1984). There are well-defined categories of geological processes responsible for the formation of all minerals and rocks, and industrial minerals and rocks encompass the complete spectrum. Such a classification parallels standard geological understanding and has exploration relevance because a commodity may be found again in other places where these processes

Source: Anon. 1994.

Figure 1. Industrial mineral deposits found in active continental margins

dominate. Because particular geological processes often result in a range of similar products, there is also some natural grouping of physical properties, although this is far from uniform.

The dominant divisions have been igneous, sedimentary, metamorphic, and surficially altered minerals and rocks (Harben and Bates 1984). Igneous subdivisions were intrusive, extrusive, pegmatitic, and hydrothermal; sedimentary was divided into clastic, biogenic, and chemical. Because this is principally a geological categorization, waste and processed materials were not specifically addressed. In their follow-up account of world deposits (and after much deliberation; P. Harben, personal communication), the same authors reverted to an alphabetic arrangement of commodities, allowing very different deposit types to be discussed under individual commodity headings (Harben and Bates 1990).

Lorenz (1991) produced a more detailed tabulation of geological origins for industrial minerals deposits, along with a similar analysis of deposit sizes and many other economic, technical, and end-use parameters.

Tectonic Models

Although mainly developed as exploration models, these block diagrams have, in effect, produced a tectonic classification of deposit types for particular commodities (Figure 1; Anon. 1994; Highley

1994). They are therefore a development of the geological process classifications and have the major advantage of allowing analysis of the potential spatial, as well as geological, relationship between different industrial minerals. This makes the approach an ideal one for industrial minerals exploration and parallels the earlier work undertaken for metal deposits (e.g., Mitchell and Garson 1981; Sawkins 1984).

Important Properties

As the phrase “industrial minerals and rocks” implies, each commodity has some commercially significant composition or property on which its use is based. Kline (1970) devised a simple twofold division: *chemical minerals*, where their main purpose is as the source of important elements (e.g., industrial minerals and rocks used in the fertilizer, chemical, ceramics, and metallurgical industries); and *physical minerals*, where the minerals do not significantly change in composition during use. Important features of this latter group, which include many construction materials, abrasives, foundry supplies, gems, and fillers, would be their physical properties such as particle-size distribution, brightness, and surface area.

These considerations have become central to many later classifications but usually as one part of a more complex set of classification criteria.

End-Use Classifications

It is a common saying in the industrial minerals and rocks sector that “exploration begins with markets” (Coope 1982). This highlights the essential importance of understanding that the mineral or rock has value only if there is a customer willing and able to pay for it. Minerals are, however, capable of being utilized in many different end uses; limestone, for example, can provide more than 100 separate products that are used in very different applications. Equally, some consuming industries require a suite of different industrial minerals, each of which alone would not meet the needs of the manufacturing process. For these reasons, many classifications have concentrated on either the end uses for minerals and relationships between them, or combined end uses with other important parameters of the industrial minerals and rocks industry.

Following the work of Bates (1959) and Wright and Burnett (1962), Fisher (1969) conducted a detailed analysis and defined six major end-use groupings that were characterized by variation in unit value, production volume, and associated parameters:

1. Bulk construction and building materials
2. Bulk ceramic raw material (in addition to lime and diversified industry raw materials or products)
3. Specialty building products and principal refractories
4. Major industrial chemicals and fertilizer raw materials
5. Industrial minerals and rocks
6. Specialty-grade and precious minerals and rocks

For each group, Fisher also presented a series of graphs showing the typical levels of capital and plant cost, place value, resource spread, enrichment ratios, and fiscal treatment, based on deposits and companies in the United States. Although the groupings are defined on end uses, this represents one of the earliest and most rigorous attempts at a multifaceted classification for industrial minerals and rocks.

In a major review of nonmetallic mineral deposit assessment criteria, Lorenz (1991) produced a detailed tabulation of commodity uses in some 38 products or intermediate products. Highley (1994) adopted a more straightforward graphical attempt to illustrate important sectors with a hierarchical chart of major end users. Chang (2002) also produced an account of the industrial processes and end uses for the main industrial minerals and rocks and noted that they could be allocated into 16 groupings based on their function or final product.

Although not an attempt at a rigorous classification, the end uses for ground (filler and extender) minerals are examined from a “formulator’s” viewpoint in Ciullo (1996). Although this represents only a section of both consuming industries and industrial minerals and rocks, it provides a useful way of examining the diverse roles that different minerals play in products and their ability to substitute for each other.

Economic

As part of their objective to inform Californians about their state’s geology, mineral deposits, and general usefulness of minerals and rocks, Wright and Burnett (1962) proposed a threefold “commercial” classification of industrial minerals and rocks. Based on unit price and production volumes, the groups were

1. Low price–large volume: materials used in construction such as aggregates, gypsum, and common clay
2. High price–high volume: borates, potash, and salt
3. High price–low volume: barite, kyanite, beryl, mica, and talc

Each group was also identified as having a number of common features in terms of their deposit size, distribution, location, mining methods, and treatment.

Table 1. Industrial minerals and rocks classification based on end use and genetic subdivision

Aspect	Group 1	Group 2
Bulk	Large	Small
Unit value	Low	High
Place value	High	Low
Imports and exports	Few	Many
Distribution	Widespread	Restricted
Geology	Simple	Complex
Processing	Simple	Complex
	Industrial Rocks	Industrial Minerals
	Igneous Rocks	Igneous Minerals
	Basalt and diabase	Beryl
	Granite	Feldspar
	Perlite	Lithium minerals
	Pumice and pumicite	Mica
		Nepheline syenite
	Metamorphic Rocks	Vein and Replacement Minerals
	Marble	Barite
	Slate	Fluorspar
		Magnesite
	Sedimentary Rocks	Quartz crystal
	Clay	Metamorphic Minerals
	Gypsum	Asbestos
	Limestone and dolomite	Graphite
	Phosphate rock	Talc
	Salt	Vermiculite
	Sand and gravel	Sedimentary Minerals and Sulfur
	Sandstone	Borates
		Diamond
		Diatomite
		Nitrates
		Potash minerals
		Sodium minerals
		Sulfur

Adapted from Bates 1969.

Bates (1969) developed his own twofold subdivision based on an analysis of similar high and low unit-value commodities. This also involved examining the bulk, place value, imports and exports, and distribution and geological or processing complexity that typified each group. He concluded that because most *industrial minerals* fell into the high unit-value group, while *industrial rocks* mainly fell in the low unit-value group, these should form the basis of a simple classification. In this scheme, rock salt is regarded as a rock, while potash a mineral—a slightly arbitrary attribution that fits better with the typical characteristics of other commodities within each group (Table 1).

From a systematic economic perspective, Noetstaller (1988) produced a highly illuminating analysis of the industrial minerals and rocks sector in his report for the World Bank. Although again not principally for classification purposes, the lists and graphs produced for ranking and economic comparisons offer much insight into the ranges and clustering of industrial minerals and rocks commodities under many economic, trade, technical, and even geological parameters. Examples include commodity lists by unit value, concentration of production in certain countries, the proportion of each commodity’s production that is traded internationally, and a

contrast of commodity production and consumption between the developing and developed world. An update of this World Bank report would be of great service to the industry.

Hybrid and Combined Methods

Bates (1960, 1969) produced a combined end-use and genetic classification incorporating a simple initial division into industrial rocks or industrial minerals, with duplicated geological subdivisions denoting the origin within each (see Table 1).

To attempt to relate geological and economic factors, Dunn (1973) developed a matrix classification in the form of a chart with one axis as uses and processes, and the other as rock types and minerals. The matrix incorporates the split by importance of either physical or chemical property (similar to Kline 1970), with 23 general end-use subdivisions, against which are indicated specific rocks or minerals used and their geological origins (similar to Bates 1969). The main strength of this chart was to visually highlight the versatility of some rock or mineral products, the geological environments that provided a range of economically interesting products, and the end uses that exploit many alternative or complementary mineral raw materials.

Kuzvart (1984) undertook a thorough comparison of different principles on which classifications have been constructed. He favored a classification system based on a combination of genetic, end-use, and economic aspects of industrial minerals. This was achieved despite the observation that an understanding of the genesis, end uses, and economics of deposits develops continually, requiring frequent revision of a classification based on these factors. He did, however, organize his work to encompass the twofold economic classification of Bates (1969), with an alphabetic subdivision of commodities supplemented by separate chapters addressing genetic, prospecting, and technological factors.

As a tool to assist in teaching about industrial minerals and rocks, Smith (1999) developed a classification that defined seven groups of commodities based on the relative importance of physical and chemical applications or a combination of the two. The classification is constructed using a matrix of commodities and uses that are grouped according to application. Clustering of commodities reveals the following groupings:

1. Principal abrasives—diamond, alumina, garnet, and pumice
2. Principal refractories—pyrophyllite, sillimanite group, magnesite, and graphite
3. Principal fillers—wollastonite, titanium minerals, mica, barite, and iron oxide
4. Principal physical and chemical minerals—feldspar and zeolite
5. Mixed-application physical minerals—silica, perlite, clay, and talc
6. Principal chemical minerals—phosphate, salt, and sulfur
7. Mixed-application physical and chemical minerals—olivine, chromite, fluor spar, gypsum, and limestone

The matrix was also supplemented by a schematic representation of the groupings in the form of a set of intersecting circles.

Other Classifications

Industrial minerals are included and subdivided in all manner of other classifications, from depletion allowances to tax rates, under import duties and Bureau of Statistics classifications, and in a multitude of economic categories. These generally do little to illuminate industrial minerals and rocks as a group and will not be considered in any further detail here.

LIMITATION OF THESE APPROACHES

To exploit an industrial mineral deposit successfully, all factors need to be considered, including deposit location, quality, processing amenability, other essential raw materials, power, infrastructure, human resources, competition, marketing, packaging, transportation, technical support, prices, and contractual agreements. It is therefore unreasonable to expect any classification scheme to address the full range of factors that are intrinsic to or affect each commodity or grouping. The industry is dynamic; commodities rise and fall as new applications develop or cheaper and better alternatives surface. Technological advances improve bottom-line performance. A classification system must adapt to these changes. A robust classification system must address the geological, compositional, economic, and end-use properties of each commodity.

World Distribution of Industrial Minerals Deposits

Peter W. Harben

Although the crust makes up only 0.5% of the earth's total mass, it is obviously where humans live and mine and are in contact with surface waters and the atmosphere, all of which are the reservoirs and production sites for rocks and minerals. Industrial minerals are extracted in commercial quantities from the earth's silicate crust, the biosphere (water, organic substances, and skeletal matter) on land and in the sea, the hydrosphere (fresh and salt water, snow and ice), and even the atmosphere, which contains mainly nitrogen and oxygen as gases plus smaller quantities of hydrogen, carbon dioxide, and inert gases such as argon and helium.

Several methods of classifying mineral deposits have been developed, including a simple alphabetical list of the more than 2,000 identified minerals. This list can be reduced to those nonmetals that are commercially significant, perhaps 50 industrial minerals from asbestos to zircon. Mineralogically, these can be divided into different groups based on their chemical components, broadly, silicate minerals such as quartz, feldspar, and mica, and nonsilicate minerals such as oxides, sulfides, sulfates, halides, carbonates, and native elements (see Table 1). For the purpose of this chapter, however, classification according to geological and tectonic settings and subdivision by a genetic and mineral classification provides a more practical geographical flow that eliminates interference from political boundaries and oceans.

NATURAL DISTRIBUTION

With almost three quarters of the earth's crust comprising oxygen and silicon (Table 2), it stands to reason that minerals based on the SiO_4 tetrahedron—the silicates—dominate most of our surface and near-surface geology. In fact, silicates account for about 30% of all minerals and form an estimated 90% of the earth's crust. These complex silicates, many of which have commercial significance, can be subdivided based on their structures:

- Nesosilicates (single tetrahedrons) that include andalusite, sillimanite, and kyanite; forsterite and olivine; datolite; garnets; staurolite; and zircon
- Sorosilicates (double tetrahedrons) that include bertrandite
- Inosilicates (single and double chains) that include jadeite, spodumene, rhodonite, and wollastonite (all single chain); and actinolite, anthophyllite, riebeckite, and tremolite (double chains)
- Cyclosilicates (rings) that include beryl and cordierite

Table 1. Classification of minerals

Class	Type of Mineral
Elements	Metals and their alloys and the nonmetals
Sulfides	Sulfides, the selenides, the tellurides, the arsenides, the antimonides, the bismuthinides, and the sulfosalts
Halides	Fluorides, the chlorides, and the iodides
Oxides	Oxides and the hydroxides
Carbonates	Carbonates, the nitrates, and the borates
Sulfates	Sulfates, the sulfites, the chromates, the molybdates, the selenates, the selenites, the tellurates, the tellurites, and the tungstates (or the wolframates)
Phosphates	Phosphates, the arsenates, the vanadates, and the antimonates
Silicates	Silicates (the largest class)
Organics	Minerals composed of organic chemicals
Mineraloids	Minerals that lack crystal structure

Table 2. Abundance of elements in the earth's crust

Element	Approximate % by Weight	Cumulative Percentage
Oxygen	46.6	46.6
Silicon	27.7	74.3
Aluminum	8.1	82.4
Iron	5.0	87.4
Calcium	3.6	91.0
Sodium	2.8	93.8
Potassium	2.6	96.4
Magnesium	2.1	98.5
All others	1.5	100.0

- Phyllosilicates (sheets) that include the clay group (chlorite, kaolinite, pyrophyllite, talc), the mica group (muscovite, phlogopite, lepidolite, and zinnwaldite), and serpentine
- Tectosilicates (frameworks) that include the feldspar, feldspathoid, quartz, and zeolite group of minerals

Among the nonsilicates, the most common classes are as follows

- Carbonates with commercial minerals such as calcite, dolomite, and magnesite; trona, nahcolite, and bastnasite; and the various nitrates, borates, and iodates
- Oxides such as anatase, brookite, ilmenite, and rutile; chrysoberyl, corundum, hematite, and magnetite; periclase, pyrochlore, and pyrolusite; stishovite, spinel, and chromite
- Hydroxides such as brucite, gibbsite, goethite, and limonite; and manganite and psilomelane
- Sulfides like pyrite and stibnite
- Sulfates like alunite, anhydrite, and gypsum; barite, celestite, epsomite, kieserite, mirabilite, and thenardite
- Phosphates like the apatite group, brushite, crandallite, amblygonite, montbrasite, wavellite, monazite, and xenotime
- Halides and chlorides like carnallite, cryolite, fluorite, sellaite, and sylvite
- Organics ranging from graphite through coal and amber to diamond
- Mineraloids that include limonite and obsidian

The relatively few elements that occur in pure or native form include gold, silver, and copper. Overall, more than 2,000 natural minerals have been identified in the earth's crust, yet only about 20 can be regarded as common, with less than a handful accounting for more than 90 % of the crust by mass (Shipman, Wilson, and Todd 2003).

Continuing with the obvious theme, Stanton (1972) concluded that most ore deposits appear to be closely related to their geological environments, and since these geological environments vary over time, it follows that particular ores should have been conspicuously concentrated in certain places at certain times during geologic history. In the metallic world, these places are known as metallogenic provinces (Govett and Govett 1976), a concept that can be applied to a more limited degree to nonmetallics. Consequently, the basic distribution pattern of mineral resources is obviously determined by geology, a premise that forms the basis for this chapter.

ANTHROPOGENIC INFLUENCES

There is, however, another layer of classification because the distribution of commercial production—that is, reserves as opposed to resources—is influenced by a diverse host of factors that include mineral grade and consistency, amenability to mineral beneficiation, geographic location, demographics, labor rates, tax and investment incentives, political stability, entrepreneurial skills, transportation options, market demands, research and development, price competitiveness, economic climate, environmental regulations, government intervention, and timing. As a result, natural and anthropogenic factors have combined to produce the distribution pattern.

The industrial minerals category includes almost 50 highly diverse, commercial, nonmetallic and nonfuel materials ranging from sand, gravel, and crushed stone (silicates) used in large tonnage and sold for a few dollars per ton (and so must be produced close to the point of use, i.e., low unit value but a high place value), to ground calcium carbonate (GCC) serving regional markets and sold at middle prices, to industrial diamond (specialized carbon) the occurrence of which in minute quantities that are thousands of kilometers from markets is no deterrent to commercial exploitation (i.e., a high unit value but a low place value). The majority of industrial minerals fall between these extremes of unit and place value—some will be able to service local, regional, and even world markets. As previously outlined, the distribution pattern of these industrial

minerals is highly skewed, reflecting the dominance of silicates and, to a lesser extent, carbonates. The distribution of supply is further reduced because commercial extraction is restricted to the land area of the continents or at most the near-shore seawater (even this continental area is distributed rather unevenly: some 65% of the total land area is in the Northern Hemisphere). The chemistry of the rocks that make up the continents and the ocean floor also differs: the mean composition of continents is close to that of granite (acid) whereas the ocean basins are formed mainly of rocks of gabbroic or basaltic (basic) composition. The seawater and atmosphere are a relatively minor but critical source of some industrial minerals such as iodine and magnesium from seawater and ammonia from the atmosphere (Dott and Batten 1988).

Just as significant today is that human resources, and therefore markets, are not distributed equally over the world. This gives rise to some interesting commercial incongruities. In certain regions, raw materials are plentiful but consumers are not, and without a market, a mineral deposit is merely a geological curiosity. Elsewhere, there may be a market but no local raw material supply. For example, despite a huge market, there is no—or virtually no—commercial production of chromite, diamonds, and manganese in the United States and Canada, or phosphate rock, diamonds, rutile, and zirconium minerals in Western Europe. In contrast, Australia with its small domestic market is the world's largest supplier of bauxite, diamonds, ilmenite, natural and synthetic rutile, and zircon. The same is true for South Africa, a leading producer of chromite, manganese, diamonds, andalusite, ilmenite, rutile, and zircon. North America, Western Europe, and parts of Asia, including Japan, Korea, and Taiwan, continue to be the largest consumers of industrial minerals. These regions completely dominate the consumption of high-technology products such as beryllium and rare earths, often importing the raw materials for conversion into specialized products that are then consumed in a local manufacturing process. On the other hand, as manufacturing activity transfers to developing countries, so too does the demand for commodity industrial minerals. Consequently, these conventional industrial minerals markets have become saturated with flat growth prospects compared with the rapid rate of growth in developing regions like parts of Asia, Latin America, and, to a certain degree, the Middle East.

Nature's uneven distribution of minerals is counterbalanced in the commercial world by the continuing growth of deep-sea international trade. More highly developed techniques of materials handling and transportation have been a contributing factor, as has the demand by consumers for materials with special or unique properties, irrespective of where these materials are found. Wyoming bentonite is delivered to oil rigs in the U.S. Gulf Coast region; soda ash from the western United States is transported via dedicated unit trains, port facilities, and ships to glass plants in the Middle East; and caustic soda from the U.S. Gulf Coast region is exported to alumina plants in Australia. Low production costs or exceptional quality products can overcome distance from market and compete successfully with more local products.

PRODUCTION PATTERNS

Contrary to the common concept of being widespread, three quarters of the worldwide supply of industrial minerals and rocks is derived from five or fewer countries (Figure 1). Curiously, even materials that appear to be virtually ubiquitous—like silica sand, gypsum, and common salt—have significant production vacuums where more than half of the world production comes from a mere handful of countries. For example, common solar salt is produced cheaply on a massive scale for export in Australia, Chile, and Mexico, where cargoes of almost 100,000 t cross thousands of miles of

Adapted from U.S. Geological Survey (data for 2000); Harben 2002.

Figure 1. Percentage of world production from five countries or fewer

ocean. The low cost of production and access to deep-water transportation allow silica sand to be exported from Queensland, Australia, to Asian markets. The most often cited example is the use of large-scale production and backhaul transportation to deliver crushed aggregate from Scotland to markets along the U.S. Gulf Coast. The recent period of rationalization has tended to reduce the number and increase the size of some suppliers. A prime example in the second half of the 1990s was when lithium, as the low-cost production of lithium carbonate from brines in Chile, replaced hard-rock mining operations in the United States and therefore severely restricted production elsewhere. Exports from China have forced producers of magnesite and magnesium, barite, fluorspar, and many other minerals, metals, and chemicals to shut down operations because consumers shopped based on price. More recently, China's domestic consumption has increased to the point where China has to import large quantities of celestite, iron ore, potash, and various potassium chemicals.

These examples all underline and expand on the obvious, but acute, truism that "the single most important fact about mineral resources is that they are not distributed equally over the world" (Flawn 1966). Once considered the "country cousins" of those glamorous metallics, industrial minerals are shedding their image of being common.

The industrial minerals can be broadly placed into geological pigeon holes (Table 3), although a number reside comfortably in several slots.

IGNEOUS INTRUSIVE

Chromite

Both olivine and chromite deposits are closely associated with ultramafic plutonic rocks. The bulk of chromite reserves occur in the large, laterally extensive stratiform or Bushveld-type for m occurring in stable shield areas as exemplified by the Bushveld

Igneous Complex in South Africa, the Great Dyke of Zimbabwe, northern Finland, and Bahia State, Brazil. In contrast, the smaller podiform or Alpine-type deposits occur in mobile belts such as the Urals of the former U.S.S.R.; the Tethyan mountain chain of the Balkans, Turkey, and Iran; and the Circum-Pacific belt. Overall, significant chromite reserves and production are restricted to fewer than 10 countries, and no metallurgical grades to still fewer, namely South Africa, the Philippines, Turkey, Greece, Finland, Albania, and India.

Olivine

Commercial olivine and dunite deposits are common in alpine-type ultrabasic terrains. A limited market restricts production to Norway, with 80% of world production; smaller producers are Spain, Italy, Japan, and the United States. The modest U.S. production is from North Carolina and Washington.

Nepheline Syenite

Nepheline syenite is a relatively common, silica-deficient, magmatic intrusive rock. Commercial production, however, is limited to large operations in Canada, Norway, and the former U.S.S.R. because of the limited market size, competition from feldspar, and the requirement for a consistently low iron content. Production from Canada and Norway is virtually all exported; this accounts for 70% and 30%, respectively, of world production, excluding the former U.S.S.R.

Diamonds

The primary geological habitat for natural diamond is kimberlite, an ultrabasic intrusive rock associated with stable shield regions. Diamondiferous kimberlites are concentrated in southern Africa, the Siberian Platform, Brazil, and Western Australia. Ages range from Precambrian in South Africa to Recent in Tanzania. Diamonds are

also produced commercially from placer deposits such as in Namibia (see Sedimentary section in this chapter). Overall, Africa is a prime region for diamond production, in particular South Africa, Botswana, Namibia, Lesotho, Swaziland, and Angola.

Lithium

Lithium tends to concentrate in silicic rocks and pegmatites containing feldspar, quartz, and mica in places such as Bernic Lake, Manitoba, Canada (spodumene, lepidolite); Greenbushes, Western Australia (spodumene); and Bikita, Zimbabwe (petalite, spodumene, lepidolite, eucryptite). Although lithium-rich pegmatites are separated to form a lithium concentrate plus by-product feldspar, quartz, or mica, these pegmatitic sources of lithium have been strongly challenged by lithium extracted from brines in Chile and Argentina (in fact, the availability of lithium from brines forced the closure of a hard-rock operation in the Kings Mountain area of North Carolina).

Beryllium

Although beryl is also associated with pegmatites in locations such as Brazil, the former U.S.S.R., and western Canada, production of bertrandite in Utah now accounts for 80% of the world's beryllium supply.

Fluorspar

Fluorspar is a "persistent" mineral occurring in various ore deposits, including Mississippi Valley (lead/zinc) type deposits, hydrothermal veins, stratabound or Manto deposits, contact metamorphic terrains, and alkali rock complexes. More than 50% of world production comes from China, with Mexico, Mongolia, South Africa, and Russia adding another 30%. Much of this production is exported, and the availability of attractively priced exports has forced the closure of smaller operations in North America and Europe. Other producers, largely for export, include Brazil, Kenya, Morocco, and Uzbekistan.

SURFICALLY ALTERED

Feldspathic and Silica Sands and Kaolin

Feldspar-rich deposits subject to weathering break down to form feldspathic sand deposits such as those exploited in the western United States and in Spain. Further weathering forms a mixture of feldspar, silica, and kaolin such as that mined in Bavaria. Still further decomposition through weathering or hydrothermal activity eliminates much of the mica and silica and yields premier-quality deposits of kaolin such as those mined in Cornwall in the United Kingdom, Georgia and the Carolinas in the southern United States, and the Amazon Basin of Brazil. These areas produce virtually all the coating-grade material. Other suppliers of quality kaolin include France, Germany, the Czech Republic, Malaysia, and Australia.

Vermiculite

Vermiculite is a supergene alteration product formed by the combined effects of weathering and circulating groundwater. Large-scale commercial production is confined to South Carolina and Virginia in the United States and the Palabora Complex in South Africa, which contributes 70% of world supplies. Minor quantities come from China, Russia, Brazil, Zimbabwe, Japan, Australia, and Egypt.

Bauxite

Because residual bauxite deposits result from the tropical weathering of a variety of source rocks, their distribution is based on clima-

tology rather than lithology. Formation is encouraged by long periods of tectonic stability permitting deep and thorough weathering. Most bauxite deposits are post-Cretaceous in age and many occur in modern tropical regions. Bauxite provinces have been defined as follows:

- Guiana Shield of South America (Venezuela, Guyana, Surinam, Guiana, and parts of Brazil and Colombia)
- Northern Brazilian Shield Province
- Caribbean Shield Province (Costa Rica, Jamaica, Dominican Republic, Haiti, and Puerto Rico)
- Guinea Shield Province (Guinea-Bissau to Togo)
- Cameroon Province (Cameroon, Zaire)
- Australian Province
- European Province (France, Greece, Hungary, and Yugoslavia)
- Others (United States, China, former U.S.S.R., India, and Malaysia).

A dozen countries contribute 95% of world production, with more than 75% coming from Australia, Guinea, Jamaica, China, and Brazil. Nonmetallurgical grades used for refractories, abrasives, chemicals, and aluminum cement are confined to specific deposits in China, Australia, Guinea, Brazil, Guyana, and Suriname.

Manganese

Manganese is found in most geological environments; the commercially more important being sedimentary and residual. Large sedimentary marine deposits of manganese are exploited in Ukraine, the former U.S.S.R., the Kalahari Basin of South Africa, Groote Eylandt in Australia, and Mexico. Residual deposits are important in Ghana and Gabon in West Africa and in Amapá, Brazil. More than 90% of world production comes from eight countries—China, South Africa, Ukraine, Brazil, Gabon, Australia, India, and Kazakhstan. Nonmetallurgical grades constitute a relatively small percentage of output from these major suppliers, plus smaller tonnage producers such as Ghana, Morocco, and Greece.

Iron Oxides

Iron oxides are generally associated with volcanic activity and sulfide deposits combined with subsequent leaching and diagenic alteration. India is the world's largest supplier with more than 70% of production, followed by the United States with an additional 10%. European production is centered in Spain, United Kingdom, France, Italy, and Austria (the last being the main source of natural micaceous oxide). Cyprus is noted for its variety of iron oxides, including ochre andumber.

Tripoli

Tripoli is a microcrystalline, friable, high-silica (98% to 99%) material formed from the weathering of siliceous limestone. The only large-scale commercial producers are in the United States, specifically the southwestern Missouri–northeastern Oklahoma region, southern Illinois, and the Ouachita Mountain region of Arkansas. Deposits in the latter region are associated with novaculite.

Zeolites

Natural zeolites are formed through the reaction of pore water with volcanic glass, clay, feldspar, and a variety of other rocks and minerals. Although zeolites have been recognized in virtually all parts of the world, large-scale commercial production is restricted to the western United States, Cuba, Japan, and several eastern European countries, including Bulgaria.

VOLCANIC EXTRUSIVE

Perlite

Because of susceptibility to devitrification and alteration, commercial deposits of extrusive volcanic rocks like perlite and pumice are generally confined to younger geological terrains. Perlite deposits, which are rarely older than Oligocene, are exploited in the western United States, Mexico, Greece, Turkey, Italy, western Russia, Hungary, the Czech Republic, and Japan. Among them, the United States (particularly Arizona, New Mexico, and Nevada) and Greece account for more than 60% of world production and, in fact, Greece exports product to eastern U.S. markets.

Pumice

Pumice is common on volcanic islands such as Lipari near Sicily, Yali and Nisissos in Greece, and the Canary Islands of Spain. Italy, Greece, and the United States control more than 50% of the world's pumice supply. Smaller tonnages come from Chile, Germany, Spain, Turkey, Italy, New Zealand, France, Ecuador, Ethiopia, Guadeloupe, Iran, Martinique, Argentina, and the Dominican Republic (production from some areas may include volcanic tuff, ash, pumiceous lapilli, or scoria).

SEDIMENTARY

Silica

Sedimentary deposits are formed through the erosion, transportation, and redeposition of minerals that can survive the rigors of transportation. The most common is silica, which forms a number of materials, including silica sand, sand and gravel, and flint. The precursor is igneous quartz (e.g., in granite), and then the sedimentary deposit may undergo metamorphism and recementing to produce quartzite. Sand and gravel for construction use is extremely common, and production is more dependent on local markets than availability. Certain areas are, however, noted for producing industrial sand that is sufficiently pure to be used in the manufacture of glass, ceramics, sodium silicate, and the like. Examples include the midwestern United States; Badgeley Island, Ontario, Canada; Cheshire in northwest England; certain areas of Belgium and the Netherlands; Cape Flattery Island, Queensland, Australia; and Sarawak, Malaysia. In many cases, the use of local sand is based on price rather than quality. The United States is the largest producer of industrial sand, accounting for more than one quarter of world production. Production of flint is much more restricted, based largely on the chalk deposits of southern England and northern France.

Clays

Several clays composed mainly of kaolinite are of sedimentary origin. Premier deposits of ball clay, the carbon content of which indicates that it was deposited in swampy conditions, occur in the Kentucky–Tennessee area of the United States, Devon in southwest England, and the Czech Republic. Flint clay, as produced commercially in the United States, China, Australia, and Argentina, is generally derived from the weathering of soil and deposition in shallow basins. Fire clay or refractory kaolin is a kaolinite material common in many parts of the world, particularly in association with coal deposits. A 400-km belt of kaolinite-rich rocks extends from Aiken, South Carolina, to Eufaula, Alabama, and includes areas supplying high- and medium-quality kaolin and refractory kaolin. Another belt of kaolin, bauxite, and bauxitic and kaolinitic clays extends from western Tennessee into northeastern Mississippi. Other areas include southwest England and over the English Channel in France (kaolin and ball clay); various parts of the Czech Republic (kaolin and ball clay); Spain; the Amazon Basin in Brazil (bauxite,

kaolin); Japan (kaolin, refractory clay, roseki, and tosek i); and Queensland, Australia (bauxite, kaolin).

Volcanic ash deposited as part of a sedimentary sequence eventually forms sodium or calcium bentonite. Important bentonite deposits occur in the United States in the Wyoming–Montana region (sodium-based bentonite) and in the Mississippi–Texas region (calcium-based). Almost 40% of the world's bentonite production is from these and some smaller deposits in the United States. More modest tonnages are produced in Mexico and Canada. In Europe, bentonite is mined on Milos Island in Greece, Turkey, Sardinia in Italy, Bavaria in Germany, southwestern England, Ukraine, and Spain. In Asia, production is centered in Japan, India, and China. Attapulgite and sepiolite (fuller's earth) are more restricted, being produced in Georgia and Florida in the United States (75% of world production), Germany, the United Kingdom, Senegal, and Spain.

Titanium and Zirconium Minerals (and Rare Earths)

Placer and palaeo-placer mineral deposits are important sources of heavy minerals such as ilmenite, rutile, and zircon. The rare earth sources monazite and xenotime are invariably associated with the mineral sands deposits. Many titanium/zirconium/rare earth mineral deposits are Tertiary and Quaternary in age because this was a period of geological uplift that provided the correct conditions for accumulation, plus the fact that older examples have been destroyed. Most placer deposits are in marine sand deposits along or near present coastlines, where they are concentrated by a combination of tidal action, longshore currents, waves, winds, and natural traps such as a cape. Most commercial placer deposits are recent beaches and dunes along coastlines, with some older deposits being stranded by land elevation or ocean withdrawal. Important areas include the east and west coasts of Australia, parts of Florida and Georgia in the southeastern United States, around Richards Bay in South Africa, Sierra Leone in Africa, the coastal areas of Tamil Nadu and Kerala states in southern India extending into eastern Sri Lanka, and the coastal areas of Brazil. Consequently, supplies are dominated by Australia with 45% of the ilmenite supply, 100% of the leucoxene, and more than 50% of the rutile, followed by South Africa, the United States, Ukraine, and India. Hard-rock ilmenite deposits are exploited in Quebec, Canada, and Norway. Except for the United States, most of the production is exported for use in the production of titanium dioxide pigment.

Diamonds

Major diamondiferous beach placers extend along the southwest coast of Africa and are exploited in South Africa and Namibia.

BIOGENIC

Limestone and Dolomite

Limestone is an extremely common rock formed as shell beds on a shallow sea floor. Purity depends on the environment of deposition and the subsequent mineralogical and tectonic history that may include metamorphism to marble. Limestone is exploited for uses ranging from construction aggregates and railroad ballast to cement and lime manufacturing, and glassmaking to GCC used as functional fillers in paper, plastics, and paint. The relatively modest price even for the high-calcium and high-brightness grades of GCC (less than \$200/t) means that consumption is generally close to the point of production (i.e., a local or regional market). In the United States, for example, crushed limestone is produced in all states except for Louisiana (which does produce shell), includes more than 2,500 quarries, and accounts for two thirds of the nation's crushed stone output. High-quality, filler-grade GCC produced in

Vermont, Massachusetts, and Ontario in Canada serves many parts of the United States, including the Northeast, Maryland, the mid-Atlantic states, Georgia, Alabama, Illinois, Texas, California, and Washington. In Western Europe, chalk is important in the United Kingdom, France, and Belgium, whereas crushed marble is often used in Italy and Greece.

Dolomite has many of the uses outlined for limestone, plus several others, including in refractories, in seawater magnesia and magnesium metal production, and as a dimension stone. Although less common than limestone, dolomite production, particularly for aggregates, is extremely widespread. In the United States, nonaggregate production is concentrated in California, Ohio, Michigan, Alabama, Texas, Connecticut, and Pennsylvania. Europe has an active dolomite industry where it is used extensively as a raw material for refractories and seawater magnesia production. The main producers are Spain, the United Kingdom, Belgium, France, Germany, Norway, Sweden, and Finland.

Diatomite

Diatomite deposits are formed through the accumulation of the frustules of diatoms, small animals that thrived after the Cretaceous period. Diatoms require marine or freshwater rich in nutrients like phosphates, nitrates, and silica, and relatively free of sediment. In many cases, the diatomite is associated with volcanic activity, which may be the source of silica. Important diatomite production sites include the western United States—especially California, Nevada, Washington, and Oregon. Almost three quarters of the world's production comes from the United States, China, Japan, and Denmark (although the last produces mainly molar, an impure diatomite product). Other producers are Spain, Germany, Italy, Iceland, and Korea.

Phosphate Rock

The bulk of commercial phosphorus-based compounds are derived from marine sedimentary phosphate rock deposits, with much of the rest derived from igneous deposits. Sedimentary phosphate deposits are concentrated in two main belts, the trade-wind belt that is aligned north-south from the equator to 50° latitude, and the equatorial belt, oriented west to east in low latitudes. In the trade-wind belt, deposits are located in the southeastern and northwestern United States (Florida, North Carolina, and Idaho); Baja California, Mexico; Sechura Desert, Peru; and the Caribbean Sea. In the equatorial belt, deposits are found in North Africa (Morocco, Tunisia, Algeria, Togo); the Middle East (Jordan, Israel, Syria, Senegal, Iran); the former U.S.S.R.; Venezuela; and Colombia.

More than 80% of the world's phosphate rock production comes from the United States, Morocco, China, Russia, Tunisia, and Jordan. Morocco is particularly important because it is the leading exporter. A series of middle-range producers include Brazil, Israel, Togo, and South Africa. The production in Russia, Brazil, and South Africa is largely derived from igneous deposits that may also yield rare earths, vermiculite, or copper.

Sulfur

The discretionary extraction of sulfur has declined as more and more production is based on nondiscretionary by-product sulfur extracted to comply with environmental regulations at nonferrous smelters and roasters, natural gas and crude petroleum processing plants, coking plants, and the like. Native sulfur associated with the cap rock of salt domes and in sedimentary deposits is still mined by the Frasch hot-water method (mainly in Poland but no longer in the United States), and the mining of pyrite as a source of sulfur is restricted to China.

CHEMICAL (EVAPORATE) MINERALS

Certain minerals are found dissolved in seawater and various other brines; evaporate deposits form when the concentration reaches saturation and precipitation occurs. This process requires favorable conditions such as a barred basin or broad shelf environment, plus a hot, dry climate that encourages evaporation. Once formed, the fragile deposit needs to be preserved in subsequent geological events such as burial. Halite, gypsum, and anhydrite, often interbedded with limestone and dolomite, are the most common minerals present in marine evaporates, which often extend over hundreds of square kilometers and attain a thickness greater than several thousand meters. In rarer cases, other evaporate minerals are present, such as potassium minerals, borates, and strontium minerals.

Salt

Common salt lives up to its name by being ubiquitous in most brines and many evaporate deposits. It is exploited commercially from seawater where the modern climate allows evaporation (e.g., in Western Australia, Mexico, Bahamas, Netherlands Antilles, Chile, India, Brazil, Italy, and Spain). Large, buried rock salt and salt dome deposits are important in the northeastern, southern, and midwestern areas of North America; central and northern Europe; parts of the former U.S.S.R.; and the Middle East. Saline lakes are worked in the western United States, for example, the Great Salt Lake in Utah (which yields or has yielded sodium sulfate, potassium minerals, magnesium chloride, bromine, and lithium as well as salt) and Searles Lake in California (sodium sulfate and borates). Despite the widespread production of salt, three quarters of the world's production is accounted for by the United States, China, Germany, India, Canada, Mexico, Australia, France, Brazil, Chile, and the United Kingdom.

Other Sodium Minerals

In addition to salt, other sodium-rich minerals are concentrated in modern brines or evaporate deposits. Vast deposits of natural sodium carbonate or trona around Green River, Wyoming, yield more than 10 Mtpy of refined soda ash and form a soda feedstock for a variety of chemical products. Smaller deposits are known in China and Turkey. Sodium carbonate is also extracted from saline lakes in the western United States, Mexico, China, Russia, and Africa. Lake Magadi, Kenya, which has been producing sodium carbonate for most of the last century, is one of numerous sodium-rich lakes in the 6,030-km rift valley stretching from Turkey through Arabia and East Africa to Tanzania. This valley also includes the Dead Sea (dividing Israel and Jordan), which currently produces salt and potash and has the potential to produce sodium carbonate, magnesium oxide, and bromine. Natural soda ash production constitutes almost 30% of total world production (virtually all from the United States), with the balance produced in Solvay plants using a salt and limestone feedstock.

Sodium sulfate is a common co-product in brine-based operations. In addition, natural sodium sulfate is exploited from lakes in western Canada, in California in the United States, and in Mexico, Russia, and Turkey. Buried deposits are mined in Spain. Sodium sulfate is also a by-product of several industrial processes, including rayon manufacture. Although production is broad based, more than 50% is in China, the United States, Spain, Mexico, and Belgium.

There are three important commercial sulfate minerals—gypsum (calcium), celestine (strontium), and barite (barium). In North America, large deposits of gypsum occur in the Northeast (New York in the United States and Ontario and the Maritime provinces in Canada), Midwest (Michigan, Iowa, and Indiana), and the Southwest and West (Oklahoma, Texas, Kansas, New Mexico, and

California). In the U.S. Gulf Coast region, accumulations of salt, gypsum, and sulfur stretch into Mexico. Overall, the three countries in North America account for a third of world gypsum production. In Australasia, China, Japan, Thailand, and Australia contribute more than 20% of world production; and in Europe, the large evaporate deposits previously outlined also contain gypsum, with the main suppliers being France, Spain, Germany, and the United Kingdom. Production in the Middle East is dominated by Iran. Several countries such as Germany produce gypsum as a by-product from flue-gas desulfurization (FGD) or phosphoric acid plants competing with the natural product in the marketplace. Despite its low unit value, gypsum is often exported on a large scale from coastal locations in Mexico, Canada, and Spain to the United States.

Potassium Minerals

In some cases, potassium minerals are found associated with salt. During the Permian period in Europe, for example, the Zechstein Basin extended from northern Britain through the Netherlands, Denmark, and Germany to Poland. This was a shallow stable sea that allowed thick evaporate sequences to accumulate, resulting in the large potash and salt deposits that are exploited today. To the east, three basins contain vast reserves of potash—Stebnik/Kalush in Ukraine near the border with Poland, Soligorsk near Minsk in Belarus, and Solikamsk/Berezniki west of the Urals. In western Canada during the Silurian to mid-Devonian period, the land subsided to form a large basin stretching southward into the United States. This allowed vast thicknesses of evaporates to be formed, including the potash resources of Saskatchewan, Canada. A large potash/salt-rich basin identified in Thailand has potential for commercial production. Despite its strategic importance as a fertilizer, large-scale potash production is fairly restricted with just 10 countries—Canada, Russia, Germany, Belarus, Israel, the United States, Jordan, the United Kingdom, Spain, and Brazil—accounting for 97% of world production.

Celestite

Virtually all the world's celestite is mined in just six countries—Mexico, Spain, Turkey, Argentina, Iran, and Pakistan. In northern Mexico, the output from several mines accounts for half of the world's production; Spain contributes an additional 40%.

Barite

As mentioned previously, barite can be associated with evaporate minerals such as celestite and gypsum. In addition, barite is also found as a hydrothermal vein filling associated with stratiform massive sulfide deposits and as a residual deposit. China has emerged as the world leader in barite production, accounting for more than 50% of the world total. In contrast, barite production in the United States has declined to 6% of world production because of the availability of imports from China and, to a lesser extent, Mexico and Morocco. Other suppliers are India, Iran, and Turkey.

Borates

About 60% of the world's borate production is controlled by the United States and Turkey, with Argentina, Chile, and Russia supplying most of the balance. Part of the production is based on brines and encrustations in Searles Lake, California, and from small concentrations along a stretch of the Andes Mountains encompassing Argentina, Bolivia, Chile, and Peru. The major source of borate minerals is a buried mass of sodium borate at Boron in the Mojave Desert of California. Other buried and surface borate deposits occur in Death Valley, including the Billie colemanite deposit, which was mined until the mid-1980s. In Turkey, borates are concentrated in

six areas—the most important being the Emet and Kirka areas (both sodium borate) and the Bigadiç area (calcium borates).

Lithium

In addition to hard-rock deposits already described, lithium may be enriched in some geothermal waters (for example, Imperial Valley, California, United States; Reykjanes Field, Iceland; and Wairekei, New Zealand) and oil-field brines (Paradox Basin, Utah; Smackover Formation, Arkansas; and Texas—all in the United States). Brines may be further concentrated in saline lakes or salars if given an enclosed basin close to Tertiary or Recent volcanoes, a desert environment, and time for accumulation and enrichment. Major lithium-producing salars include the Salar de Atacama in Chile (which contributes more than 50% of world production); Salar del Hombre Muerto in Argentina; and Silver Peak, Nevada, in the United States.

Magnesia

In addition to magnesite, dolomite, and olivine, magnesia is concentrated in subterranean and seawater brines. Magnesium-rich brines are exploited on a commercial scale in Michigan in the United States, and in Mexico, the Netherlands, and Israel. Magnesia is also extracted from seawater in Japan, South Korea, the United States, Mexico, the United Kingdom, France, Italy, Ireland, Norway, and Russia.

Nitrates

Natural nitrate production is now confined to an area of northern Chile that has an annual rainfall of less than 1 cm. In addition, iodine is co-produced from the caliche ore and accounts for more than 50% of world production. Elsewhere, commercial iodine production is based on brines largely found in Japan (35% of world production), the United States (Oklahoma), China, Azerbaijan, Russia, and Turkmenistan. Bromine is also extracted from well brines in Arkansas and Michigan in the United States, the Dead Sea in Israel, potash brines in Germany and France, and seawater in the United Kingdom, France, Spain, and Japan. The United States and Israel combine to account for 75% of world production.

METAMORPHIC

Metamorphism produces a range of minerals, many of which have unique properties that are used commercially.

Asbestos

Asbestos is found in several metamorphic environments usually associated with ultramafic rocks and serpentinization. Large deposits are exploited in Quebec, eastern Canada; in the Transvaal and Cape Province of South Africa and in Swaziland and Zimbabwe in Africa; Russia, Italy, and Greece in Europe; New South Wales in Australia; Brazil; Kazakhstan; and India.

Talc

China produces about 50% of the world's talc and is a major exporter. The United States and Canada account for about 12% of world talc production with output from Vermont, upstate New York, Montana, Texas, and California in the United States and Quebec and Ontario in Canada. In Australasia, China is by far the largest producer, followed by India, North and South Korea, Japan, and Australia. In Europe, significant talc producers include France, Italy, Austria, Finland, and Norway, along with Russia. In South America, Brazil is the largest producer. Table 4 shows the major suppliers in the world minerals market.

Table 4. Major suppliers of industrial minerals (more than 20%)*

Country	Mineral	Total	World Production, %
Australia	Titanium concentrates (leucocoxene), <i>t</i>	27,000	100

† REO = rare earth oxides.

Wollastonite

Wollastonite is formed through the metamorphism of rocks containing silica and calcium. Major producing areas of high-quality wollastonite include the Adirondack Mountains of upstate New York in the United States, southeastern Finland, several provinces in China and India, and Russia.

Garnet

Garnet is associated with some wollastonite deposits, including one at Willsboro, New York. In the same area of the state, a large-scale hard-rock garnet mine is in operation. Elsewhere in the United States, although there are hard-rock garnet deposits in Maine and Nevada, the most important commercially are placer deposits in Idaho. Garnet is also produced as a by-product of mineral sand operations in Western Australia, India, and Sri Lanka.

Kyanite Group

The kyanite group of minerals occurs in aluminous metamorphic rocks and their weathered derivatives. Production is restricted to a handful of countries, including South Africa, Russia, the United States, France, India, Sweden, Spain, China, and Zimbabwe. Like garnet, some are found associated with placer mineral sand deposits, particularly in India.

Pyrophyllite

Weathering may form sericite or pyrophyllite, the hydrous aluminum silicate. The main pyrophyllite deposits, however, are formed through the hydrothermal alteration of acidic volcanic rocks. This is particularly well developed in areas of Japan and the Republic of Korea—accounting for 85% of world production between them. Smaller producers include Canada, the United States, India, China, Thailand, Australia, Brazil, and Argentina.

Corundum

Natural corundum is another alumina-rich mineral formed through metamorphism. The main producers are Zimbabwe and South Africa, the former U.S.S.R., and India. Production of the impure form, emery, is restricted to Turkey and Greece.

Graphite

When certain organic matter is metamorphosed, deposits of graphite can form. Although world production is concentrated in fewer than 20 countries, more than 60% is produced in Asia—China, the Republic of Korea, Sri Lanka, and India. In the Americas, Mexico and Brazil are well-established producers, and Canada is emerging as a major supplier. The main producers are Germany, Austria, the Czech Republic, Norway, Romania, Turkey, and Russia in Europe, and Zimbabwe and Madagascar in Africa.

THE EMERGING PATTERN

The uneven distribution of industrial minerals and rocks and their production counters the concept of a group of common, low-priced commodities destined for local markets (see Tables 5 and 6). Local markets are the most important for some industrial minerals, especially for developing countries, which should adopt simpler approaches to exploiting their domestic resources. Nevertheless, the overall view of industrial minerals is an international one of intriguing complexity.

For instance, production of borates, beryl, iodine, nepheline syenite, celestite, and vermiculite is restricted to just a few countries, and essential materials such as titanium, zirconium, rare earth minerals, sulfur, graphite, phosphates, and potash are extremely

active in deep-sea trade. Even relatively common materials enter international trade as consumers demand higher and more consistent quality (feldspar and silica sand) or find it more cost-effective to import (soda ash, salt, barite, gypsum, and fluorspar). The international supply-and-demand pattern is dynamic as new producers and markets come and go. Twenty years ago, Australia's diamond industry was a kimberlite pipe dream; today it accounts for 20% of gem quality and 30% of industrial quality diamonds. A generation ago, celestite was used solely for pyrotechnics; today the much larger market is dominated by glass for color television screens.

Substitution has always been an important aspect of the industrial minerals scene and continues to be critical for success. For example, in the paper industry, calcium carbonate is a major challenger to kaolin as a filler and coater, and precipitated calcium carbonate competes with GCC in many applications. In certain parts of the world, most notably in Scandinavia, talc is a potential substitute for both carbonate and kaolin. Regional bans on the use of phosphates in detergents encouraged the use of synthetic zeolites that in turn aided sodium silicate producers and therefore silica sand and chloralkali suppliers. Substitution offers opportunities and dangers for potential new suppliers, although regional differences in use patterns need to be considered.

Increasingly, environmental considerations influence the supply of minerals—prime examples include sulfur and sulfuric acid recovered during the refining of crude oil and sour natural gas and gypsum precipitated from an FGD plant attached to a coal-burning power plant or the neutralization of acid in a titanium dioxide pigment plant. By-product minerals are produced as the result of a manufacturing process itself, such as sodium sulfate derived from rayon spinning or calcium chloride from the Solvay soda ash manufacturing process. The need to dispose of these minerals in a responsible and cost-effective manner encourages sale on the merchant market at low prices that in turn depress the price of any commercial equivalent or rival. By-product-generating processes driven more by economics than by environmental concerns include the electrolysis of salt, which produces equal parts of chlorine and caustic soda irrespective of the market conditions; similarly, when feldspar is separated from a granite or alkali by flotation, silica and mica are produced and sold as-is or even upgraded to value-added products. Another example would be the extraction of titanium minerals like ilmenite and rutile from mineral sands, which invariably yields monazite, garnet, zircon, and other heavy minerals. Revenues from these coproducts can be critical for the economic feasibility of the operation, even though the rate of production is not influenced by demand. It is difficult to compete with a by-product or coproduct mineral based on price alone.

Mineral-related environmental and health issues range from simple mineral dusting problems at ports to the need to label mineral content and use specialized containers to address the alleged health hazards associated with certain minerals and mineral-related products. At the very least, these issues can result in additional handling or transportation costs, create barriers to sales, impinge on the prospects for future growth, and even pose a long-term threat to the financial stability of the producing company because of the potential for litigation. Several minerals have been singled out for scrutiny—in particular, silica, asbestos, fluorspar, and bromine. Both recycling and material conservation have reduced the demand for virgin raw materials used to make everything from aluminum and glass containers, paper, and plastics to refractories, steel, and even roadbeds.

The pattern can be influenced by political events such as the opening of trade with China, which promptly became a dominant

* REE = rare earth element.

force in world markets for magnesite, talc, barite, bauxite, rare earths, and graphite. This shifting pattern of supply and demand will continue to offer future opportunities and challenges to the increasingly sophisticated industrial minerals industry. The streets of the 21st century are paved with industrial minerals, not gold. There will be more of them, and the traffic promises to be heavy.

International Trade in Industrial Minerals

Mike O'Driscoll

INTRODUCTION

From the outset, any analysis of the definition of industrial minerals at once reveals the essential dynamic that drives trade in industrial minerals; that is, market demand = mineral supply. As a consultant in the field once said, "Without a market, an industrial mineral deposit is merely a geological curiosity." So, put simply, no market demand = no mineral development = no mineral trade.

According to statistics published by the United Nations (Anon. 2004), the total value of world minerals and metal exports in 2001 was US\$166,631 million; for imports, the total value was US\$191,032 million. Industrial minerals trade contained within these figures can be roughly calculated as US\$36,452 million for world exports and US\$42,160 million for imports. These figures underline the importance and value of international minerals trade, but why are industrial minerals traded, and what influences that trade?

Industrial minerals can be defined as minerals mined and processed (either from natural sources or synthetically processed) for the value of their non metallurgical properties, which determine their use in an extremely wide range of industrial and domestic applications. In essence, wherever there is demand for these industrial and domestic applications (i.e., a market), this will create a trading business specific to that market. The crucial point is that the pattern of industrial minerals trade is dictated by the needs of the population and the performance of the economy, and then combined with mineral availability.

This chapter considers the overall nature of international trade in industrial minerals by examining the economic importance of industrial minerals, market geography, the structure of the mine-to-market supply route, pricing, and the main factors influencing mineral trade today.

THE ECONOMIC IMPORTANCE OF INDUSTRIAL MINERALS

If demand is the driver of industrial minerals trade, one must ask: Why are industrial minerals so important and where do they go? Certain industrial minerals may have 1, 2, or maybe up to 10 domestic or industrial applications; others such as lime may have more than 50 uses. To bring some coherence to industrial minerals markets, the main consuming mineral market sectors that require industrial minerals as raw materials are summarized as

- | | |
|----------------|--------------------|
| • Abrasives | • Metallurgy |
| • Absorbents | • Paint |
| • Agricultural | • Paper |
| • Cement | • Pigments |
| • Ceramics | • Plastics |
| • Chemicals | • Refractories |
| | • Synthetic fibers |
- Construction
 - Drilling mud
 - Electronics
 - Filtration
 - Flame retardants
 - Foundry
 - Glass

The individual mineral chapters detail each mineral's main application and use, but for completeness, it should be noted that the trade route of a mineral from mine to market can involve more than one stage (i.e., its consumption in manufacturing an intermediate mineral or end product), which is then consumed in the manufacture of another end product, which is then sold to an end-use market (for examples, see Figure 1).

The other aspect of many industrial minerals—that they can serve a range of markets—also affects the pattern of minerals trade, in that a single mineral source can supply several different customers because of market type and geography. For example, bentonite sourced in Wyoming travels to domestic and overseas population centers because of its widespread use as an absorbent in cat litter products. Its equally important use as a major component in drilling fluids, however, means that it is also freighted to centers of oil and gas drilling activity (e.g., the Gulf of Mexico).

MARKET GEOGRAPHY

Some of these mineral-consuming market sectors represent certain heavy industries responsible for products fundamental to a modern lifestyle. These markets can easily be identified as those that thrive in developed economies serving their populations. So, no matter where industrial minerals occur, there is a natural geoeconomic trend as to where industrial minerals are destined to be shipped and traded for use because of their economic importance. Thus, the major post-World War II modern industrial centers of North America and Europe, followed later by Japan and Republic of Korea, have been well-established market centers for minerals trade for the last half century or so.

Where there is evidence of a growing population combined with a developing economy hosting such mineral-consuming markets, these countries and regions become earmarked as growing and future markets for industrial minerals, and therefore beacons for minerals trade.

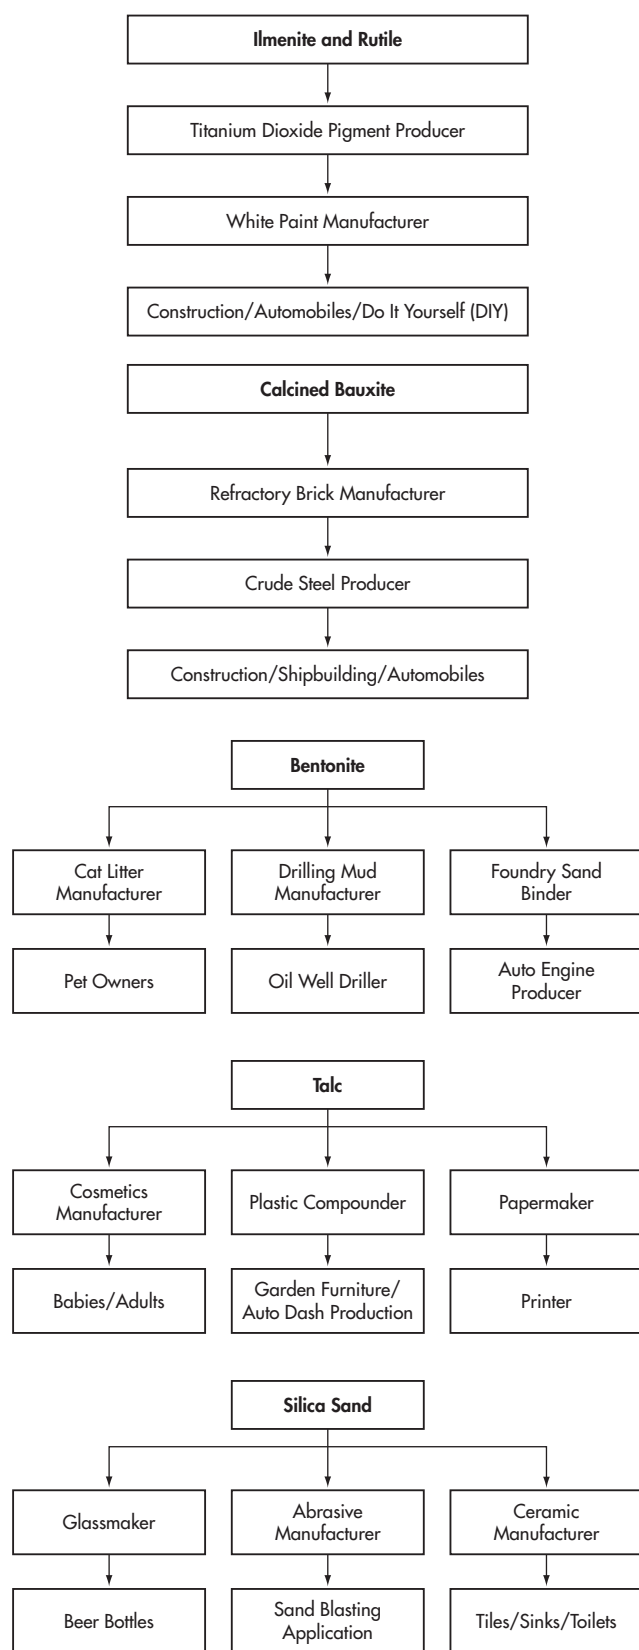

Figure 1. Examples of the trade routes for selected industrial minerals

In the 1980s and 1990s, the established markets for minerals were joined by the emerging “Asian Tiger” and Pacific Rim economies of Indonesia, Malaysia, Singapore, Taiwan, and Thailand. Since the mid-1990s, China has all but dominated world trade in commodities. India and East Asian economies, and now Vietnam, continue to grow in stature. Elsewhere, despite conflict in the Middle East, countries such as Iran are becoming stabilized as its economy flourishes and foreign investment increases. In Europe, with the breakup of the Soviet Union, it is the central and eastern European countries that are now showing good prospects for growth and demand for industrial minerals.

Once the widespread use and economic importance of industrial minerals are appreciated, it is possible to understand the chief and overriding principle of industrial minerals trade: mineral-consuming market existence and its performance directly affect demand and, therefore, trade for mineral raw materials.

Therefore, demand feeds back from the end-use market to the end product, to the intermediate end product, and finally back to the mineral supplier. Thus, the performance of the industrial minerals industry and international trade in industrial minerals is inextricably linked to three related factors: (1) centers of high population—the consumers; (2) their economies—the driver; (3) availability and occurrence of mineral resources—the source.

STRUCTURE OF MINE-TO-MARKET SUPPLY ROUTE

Once a market is established, the mineral must be sourced, a supply route can be enacted, and international trade, if appropriate, is engaged. The best way to see what really makes mineral trade function is to look at who is involved in the mine-to-market supply chain of industrial minerals.

All industrial minerals are mined (surface and under ground) and then undergo processing to refine the crude mineral ore into a processed grade or range of grades for sale to the desired market. The minerals are then transported from their source, sometimes to another plant for further processing, possibly via a complex freight route employing a raft of services, or directly to the consuming markets. In general, three broad sectors facilitate the route of a mineral from mine to market: (1) the supply sector, (2) the logistics sector, and (3) the consuming market sector.

Within each of these sectors are subsectors that have specific functions in the supply chain, employ certain types of businesses, and are influenced by different factors. Figure 1 illustrates these sectors and subsectors, and the overall mine-to-market supply chain. Take note of the influential direction of supply from the top and demand from the bottom. Other key notes to highlight are the activities and objectives of the main players in the industrial minerals market:

- **Mineral producers** seek to maintain supply to current markets and, where possible, diversify into new markets.
- **Mineral producers/processors** seek to employ and develop new processing methods to economically produce superior products for new market applications.
- **Traders, logistics companies, and consuming market mineral buyers** seek to source low-cost, high-quality minerals and alternative or new suppliers.
- **Freight and logistics** costs can be 50% to 70% of delivered cost of mineral to customer; therefore, suppliers and customers strive to secure the most cost-effective and -efficient logistics systems and companies.

The mine-to-market supply route described in Figure 2 is tailored to suit different mineral types for a range of different markets.

INDUSTRIAL MINERALS PRICING

Another important aspect of industrial minerals that requires appreciation when discussing international trade is the trade value of the minerals. Most industrial minerals are essentially high-volume, low-value commodities, whereas metals, for example, are the reverse, especially precious metals. Table 1 compares current (2005) prices.

Apart from the obvious difference in scale of value between the two sets of commodities, a key issue is the fact that unlike the metal markets whose prices are set by an exchange system (London Metal Exchange), no such facility operates for industrial minerals—despite a few ill-fated attempts made by various organizations in recent years, particularly with the advent of the Internet and e-commerce. For the reasons outlined here, it is unlikely that any kind of industrial minerals pricing exchange will be created in the foreseeable future.

Basically, the price of an industrial minerals shipment is negotiated between the mineral buyer (trader/consumer) and the seller (trader/producer). Although that might seem to be a simple concept at the outset, there is far more to industrial minerals pricing than meets the eye, and it is subject to a complex mosaic of interchangeable forces. A range of highly influential factors come into play that can affect this negotiated price and contribute to the difficulties of structuring a price exchange for industrial minerals:

- Source of mineral
- Cost of processing
- Market destination
- Volume of shipment
- Bulk or bagged
- Grade of mineral and its end use—i.e., quality of mineral, dictated by desired end use of the mineral (some minerals boast up to 50 or more grades for as many end uses; e.g., limestone used in cement is much cheaper than limestone used in paper, by approximately >\$150/t)
- Any further processing required between source and customer
- Freight and shipping—can be up to 50% to 70% of final delivered cost of mineral
- Port handling (at loading/discharge)
- Warehousing and storage
- Mineral inspection (at loading/discharge)
- Insurance
- Currency exchange rates
- Spot or long-term contracts
- Relationship between buyer and seller

There are simply too many variables to indicate a set price per grade. That said, with research and investigation, it is possible to calculate an average range of prices that largely indicate current market trading prices. For these reasons, industrial minerals prices quoted in *Industrial Minerals* and *Mineral PriceWatch*, for example, are a range of minimum to maximum prices currently traded for certain mineral grades. Minerals prices are not normally as volatile as metals prices, and price changes may be more subtle and infrequent.

The desired end use of the mineral really underlines the difference in price between grades of a single mineral. This largely reflects the degree of complexity, cost of processing, and perhaps storage of the mineral grade. Three of the examples in Table 2 (for calcium carbonate, kaolin, and zircon) illustrate the differences in pricing that result from market application.

Figure 2. Anatomy of industrial minerals trade by route of mineral from mine to market

Table 1. Price comparison of metals and industrial minerals, in US\$/t, unless otherwise indicated

Metals	Price	Industrial Minerals	Price
Gold	426.3/oz	Salt	15–18
Silver	6.78/oz	Silica sand	14–25
Aluminum HG	1,827	Olivine	50–117
Copper A	3,228	Dead-burned magnesia	157–210
Zinc SHG	1,271	Zircon	420–600

Table 2. Industrial mineral grade price comparisons

Mineral	Grade	Price
Ground calcium carbonate	f.o.b.* United States, US\$/st	
	5–7 µm	110–160
	1.5 µm, high brightness for paper	170–180
Kaolin	United States, EXW,† US\$/st	
	Filler bulk	80–100
	Paper coating	85–185
	Calcined bulk	320–375
	Sanitaryware grade, bagged	65–75
Magnesite	Tableware grade, bagged	125
	Greece, raw <3.5% SiO ₂ , f.o.b.	50–55
	Eastern Mediterranean, Euro/t	
	European caustic calcined, CIF,‡ Euro/t, agricultural grade	145–160
	China, f.o.b.t.,§ US\$/t	
Perlite	Dead burned, 94–95% MgO, refractory grade	195–210
	Caustic calcined, 90–92% MgO	140–165
	Turkey, f.o.b., US\$/t	
	Raw, crushed, graded, bulk/big bags	32–60
	Raw, bulk	14–17
Zircon	United States, EXW, US\$/t	
	Expanded, filter aid grade	210–410
	Australia, bulk, f.o.b., US\$/t	
	Ceramic grade	490–600
	Refractory grade	430–525
	Foundry sand grade	420–530

* f.o.b. = free on board; see Table 3.

† EXW = ex works; see Table 3.

‡ CIF = cost, insurance, and freight; see Table 3.

§ f.o.b.t. = free on board truck; see Table 3.

Table 3. Incoterms used in international minerals trade

CFR	<i>Cost and freight:</i> Title, risk, and insurance cost pass to buyer when delivered on board the ship by seller who pays the transportation cost to the destination port. Used for sea or inland waterway transportation.
CIF	<i>Cost, insurance, and freight:</i> Title and risk pass to buyer when delivered on board the ship by seller who pays transportation and insurance cost to destination port. Used for sea or inland waterway transportation.
CIP	<i>Carriage and insurance paid to:</i> Title and risk pass to buyer when delivered to carrier by seller who pays transportation and insurance cost to destination. Used for any mode of transportation.
CPT	<i>Carriage paid to:</i> Title, risk, and insurance cost pass to buyer when delivered to carrier by seller who pays transportation cost to destination. Used for any mode of transportation.
DAF	<i>Delivered at frontier:</i> Title, risk, and responsibility for import clearance pass to buyer when delivered to named border point by seller. Used for any mode of transportation.
DDP	<i>Delivered duty paid:</i> Title and risk pass to buyer when seller delivers goods to named destination point cleared for import. Used for any mode of transportation.
DDU	<i>Delivered duty unpaid:</i> Title, risk, and responsibility of import clearance pass to buyer when seller delivers goods to named destination point. Used for any mode of transportation. Buyer is obligated for import clearance. Seller fulfills his obligation when goods have been made available at the named place in the country of importation.
DEQ	<i>Delivered ex quay (duty paid):</i> Title and risk pass to buyer when delivered on board the ship at the destination point by the seller who delivers goods on dock at destination point cleared for import. Used for sea or inland waterway transportation.
DES	<i>Delivered ex ship:</i> Title, risk, and responsibility for vessel discharge and import clearance pass to buyer when seller delivers goods on board the ship to destination port. Used for sea or inland waterway transportation.
EXW	<i>Ex works:</i> Title and risk pass to buyer, including payment of all transportation and insurance cost from the seller's door. Used for any mode of transportation.
FAS	<i>Free alongside ship:</i> Title and risk pass to buyer, including payment of all transportation and insurance cost once delivered alongside ship by the seller. Used for sea or inland waterway transportation. The export clearance obligation rests with the seller.
FCA	<i>Free carrier:</i> Title and risk pass to buyer, including transportation and insurance cost when the seller delivers goods cleared for export to the carrier. Seller is obligated to load the goods on the buyer's collecting vehicle; it is the buyer's obligation to receive the seller's arriving vehicle unloaded.
FOB	<i>Free on board:</i> Title and risk passes to buyer, including payment of all transportation and insurance cost once delivered on board the ship (or truck—FOBT) by the seller. Used for sea or inland waterway transportation.

Aside from different units of currency and measurement (although most are now quoted in US\$/t) industrial minerals prices are quoted with several clarifying terms to determine as precisely as possible on what basis the price has been calculated. These can be taken from a plethora of abbreviated shipping terms or standardized *Incoterms*.

Incoterms are standard trade definitions most commonly used in international sales contracts. Devised and published by the International Chamber of Commerce (ICC), Incoterms is short for International Commercial Terms, which are at the heart of world trade. ICC introduced the first version of Incoterms in 1936. Since then, ICC expert lawyers and trade practitioners have updated the terms six times to keep pace with the development of international trade; the last update was on January 1, 2000. EXW, f.o.b., and CIF are

among the most frequently used Incoterms in minerals trade; Table 3 defines these and other applicable terms.

In terms of nomenclature for industrial minerals quotes, consider the following examples of price quotes:

- *Bentonite, Wyoming, EXW, USA per short ton, rail hopper cars, crude, bulk all grades US\$26–\$63* details the source of the mineral, its price in U.S. dollars per short ton as it stands ready to leave the plant (i.e., ex-works, indicating no cost yet included for freight, insurance, etc.) as a crude raw material to be shipped in bulk by rail hopper cars by the buyer.
- *Chromite, Transvaal, 46% Cr₂O₃ wet bulk, f.o.b., chemical grade US\$125–150/t* indicates chromite from Transvaal in South Africa, possessing a minimum chromia content as wet bulk material, free on board, and for chemical applications in U.S. dollars per metric ton.
- *Fluorspar, acid spar filtercake, Chinese, dry basis, CIF, US Gulf Port US\$200–210/t* indicates fluorspar from China processed as dry filtercake, with cost, insurance, and freight included in the price, delivered to a U.S. Gulf port in U.S. dollars per metric ton.
- *Refractory bauxite, Chinese, minimum 87% Al₂O₃, f.o.b., (0–50 mm, undried), Shanxi, rotary lump, BD 3.25 US\$150–160/t* indicates refractory grade bauxite sourced from Shanxi Province, China, calcined in a rotary kiln with a minimum alumina content (in percent) and bulk density value (normally expressed as grams per cubic centimeter), undried at specified lump size, free on board truck, at U.S. dollars per metric ton.

The point to note is that each mineral has its own particular set of pricing criteria that characterize a specific grade for a particular market. Often the price quote will include minimum chemical or physical properties required, depending on the mineral and its desired end use, such as the percentage content of the key performing chemical compound (as in the chromite and bauxite examples) and perhaps the bulk density (e.g., bauxite) or brightness (e.g., calcium carbonate used in paper). The price quote is normally one that is commercially recognized as standard in that specific market but may not be transferable across different grades and even less so across minerals in general.

In international minerals trade, then, each industrial mineral has not only its own tailored mine-to-market supply chain structure but also its own specific pricing criteria. Above all, because of the significance of the dynamic relationship between industrial minerals and the economy, any change in the performance of the latter can have a very strong effect on prices.

MINERALS MOVEMENT

The physical movement of minerals across the globe is naturally determined by the location of the mineral source and that of the consuming market. As has been established, market demand is a key factor in the exploitation of an industrial mineral. But because freight logistics account for such a large proportion of an industrial mineral's price tag, it is economically unfeasible for many industrial minerals to be shipped long distances. This is especially so for low-value minerals required in very large volumes (e.g., carbonate rocks for construction materials, roadstone, and cement, and the main batch materials for glass making, such as silica sand, soda ash, and limestone). As a result, many consuming markets adapt their raw material needs to the mineral sources in closest proximity.

The exception to this rule is when there are limited sources of a particular mineral in demand and few substitute materials (e.g., in early 2005, refractory-grade bauxite could only be sourced from

Shanxi and Guizhou provinces in China, and from Guyana, and the main sources of celestite are only in Mexico, Spain, and China).

Industrial mineral occurrence and distribution are covered in detail in the chapter titled World Distribution of Industrial Mineral Deposits, and individual mineral chapters highlight the main sources of minerals supply. It is not always possible to have mineral resources near centers of market demand, since nature and economic development unfortunately do not always coexist to each other's benefit. Because of this, there will always be international trade in industrial minerals. Table 4 gives examples of industrial minerals that are in constant demand worldwide but that have limited sources and thus enter the global trade network on a regular basis. The source countries, as major exporters, are highly influential in the trade of these minerals.

The one country that crops up the most is of course China, which hosts vast mineral resources and is self-sufficient in most industrial minerals; exceptions include zircon and chromite. Supply of minerals from China to world markets increased markedly during the 1980s and into the 1990s. Therise of China and East Asia as a major consuming market center in its own right, however, somewhat slowed this trade flow since about 2002.

There is another exception to the rule regarding a number of important industrial minerals that are fairly widespread in occurrence and, although produced to serve local and regional markets, still maintain a significant level of international trade. This is frequently the result of their low production costs, low labor rates, and cheap energy, which can translate to a low price per ton of final product, and thus is still competitive to ship overseas. Solar-dried salt produced in Australia is a good example. Some of the other minerals in this category are feldspar, gypsum, refractory clays, sulfur, and certain grades of calcium carbonate and silica sand.

Fused minerals such as fused alumina, fused silica, and silicon carbide are processed from natural feedstock minerals by fusion in high-temperature electric arc furnaces that consume vast amounts of electrical energy. As a result, fused mineral producers locate themselves close to low-cost sources of electrical energy, such as hydroelectric power stations. Thus, Washington Mills Electro Minerals Corp. (fused alumina, fused magnesia, silicon carbide) is based at Niagara Falls, and C-E Minerals (fused silica) and Minco (fused magnesia) are based in Tennessee. Fused materials are high-value minerals that can be shipped great distances to their end-use markets but are still profitable.

INFLUENCING FACTORS AND TRADE TRENDS

We have already highlighted some major influencing factors that affect the mine-to-market supply route and mineral pricing in international trade. In this final section, we look at some specific issues and trends that illustrate examples of interrelated factors that have had and continue to have a direct effect on industrial minerals trade.

Changing Supply Sources

If minerals are in short supply or have few worldwide sources of supply, conditions of high demand for a mineral will normally stimulate exploration and development of alternative sources, especially if older sources have matured and become exhausted or uneconomic. Once these new sources have been established, new trading routes will open.

Recent examples have included the evaluation and development of the Seqi olivine deposit in Greenland by Crew Development Corp. and Minelco AB. Interestingly, Crew already had a gold mine up and running in Greenland—a simple example of the difference in “value” between metals and minerals, whereby the price of gold ensured the success and swift fruition of the gold mining

Table 4. Examples of industrial minerals in global trade with limited sources of supply

Mineral	Source Country*
Andalusite	France, South Africa
Attapulgit	Greece, Senegal, Spain, United States
Baddeleyite	Russia
Barite	China, Morocco, Turkey
Bentonite	Greece, India, Turkey, United States
Bauxite, refractory	China, Guyana
Borates	Argentina, Chile, Turkey, United States
Chromite	South Africa
Fluorspar	China, Mexico, South Africa
Garnet	Australia, China, United States
Graphite	China
Halloysite	New Zealand
Hectorite	United States
Huntite-hydromagnesite	Greece, Turkey
Kaolin, refined	Brazil, United States
Kyanite	India, United States
Lithium minerals	Australia, Canada, Chile, Zimbabwe
Magnesite	China
Mica	China, India
Mullite, sintered	China, United States
Nepheline syenite	Canada, Norway
Nitrates	Chile
Olivine	Norway
Perlite	Greece
Phosphates	Jordan, Morocco, Russia
Potash	Belarus, Canada, Israel, Jordan, Russia
Pumice	Greece, Italy, Spain, Turkey
Rare earths	China
Sepiolite	Spain
Soda ash	United States
Talc	China, France
Titanium minerals	Australia, Canada, South Africa
Wollastonite	China, Finland, India
Vermiculite	China, South Africa
Zircon	Australia, South Africa

* Main supply sources and exporters of industrial mineral grade that influence global trade in that mineral.

project, whereas Crew's olivine project required more thoughtful evaluation of its market value (i.e., Was it economically viable? Where is the market?). With only a single major commercial source of olivine for markets in North America and Europe (i.e., A/S Olvin in Norway) and declining or small-scale production elsewhere, Crew considered that its high-quality olivine deposit might well have a chance.

Evaluation of Seqi olivine began in early 2003, and before the year was out, Minelco AB—the minerals arm of Swedish iron ore giant and large olivine user LKAB—had commissioned a bankable feasibility study from Crew and signed an agreement for an option to buy 51% of the project by funding capital development. A mining license was granted in early 2005, and mining is set to commence to bring a 1- to 2-Mtpy olivine project onstream. The site of the olivine source in Greenland means that Minelco can ship a

range of olivine grades to both European and North American markets. The European markets had been reliant on Norway (and served to a lesser extent by Italy and Turkey), whereas in the United States, in the absence of a major olivine source, iron ore pelletizing and steelmaking had switched to using dolomite as a slag conditioner. The opening and shipping of Seqi olivine is likely to change these market climates.

Elsewhere, other examples include andalusite deposits being evaluated and developed in western China and Peru as an alternative to the dominance of France and South Africa. Canadian gold miner Cambior Inc. has revived refractory-grade bauxite production in Guyana, once the leader in the field. Cambior's timing in 2004 was ideal in that the new millennium witnessed the market being hit by the double impact of refractory bauxite production ceasing in Brazil in 2003 and Chinese suppliers suffering shortages and price hikes during 2003–2005. Outside of China, Guyana is now the only other source of refractory-grade bauxite.

Zircon is another mineral whose development worldwide will create new supply routes across the globe by 2006–2010. As a high-value coproduct to titanium minerals mining, zircon is normally held hostage to the fortunes of the titanium dioxide pigment market, for which titanium minerals are supplied as raw material feedstock and thus the driver for mineral sands development. Growth in zircon markets, however, especially in ceramics, have sparked a raft of zircon-rich deposit evaluations and developments, with projects set to come on-stream in Australia, India, Kenya, Mozambique, the Gambia, and Senegal.

Economy and Market Performance—the China Factor

As ever, industrial minerals demand is shaped by national and regional economic performance. Without a doubt the dominant factor affecting industrial minerals supply and markets since the early 1990s has been China. With its opening up to the world market in 1978, the country has never looked back, and within just 25 years has evolved from a leading supplier of industrial minerals for world markets to a leading consumer and supplier of minerals. China has had a momentous effect on international trade of industrial minerals. The market growth of China and East Asia superbly illustrates the influence of new consuming market development on mineral trade routes.

Key minerals with which China bangs the world-trade drum include bauxite, barite, fused alumina, fluorspar, silicon carbide, flint clay, graphite, magnesite, talc, and wollastonite. Initially, during the mid- to late 1980s, China started to dominate world supply in these minerals, frequently triggering antidumping duties with its low-cost exports (discussed in the section on Antidumping Duties in this chapter). In the early years, Chinese minerals were not only low cost but also rather inconsistent in quality, often leading to insurance claims. This quality problem was mainly a function of outdated mineral processing equipment and techniques, a lack of independent inspection procedures, and an unstructured minerals industry that was ignorant (wittingly and unwittingly) of the risks of mixing and matching material from different sources for a single shipment. This was a gamble that consumers in the West had to take, and many, but not all, did. In the meantime, Western minerals producers would focus on maintaining customers by supplying quality-consistent, high-purity grades, but could do little about the low prices of Chinese material.

The early 1990s—with the Asian Tiger economies in full swing (albeit temporarily stalled by the financial crash of 1997)—saw a major shift in minerals-consuming manufacturing centers to East Asia. Refractories, foundry, steel, ceramics, glass, paper, paint, and plastics markets were all developing rapidly (but, at least to

begin with, at a slower pace in China itself). Leading Western manufacturers in these sectors began to set up joint-venture plants to serve these growth markets. Chinese minerals soon began to supply these East Asian countries in addition to the Western developed countries. At the same time, Western mineral companies, traders, and entrepreneurs began to establish themselves in China and Southeast Asian countries to secure and develop raw material sources to feed these markets.

The mid-1990s also witnessed a significant change in China's mineral exports in that minerals were now being exported as semi-processed or processed materials—adding value to the exports and meeting customers' requirements before shipping. This was enabled by the growth of foreign-owned minerals processors located at or near the main Chinese ports, guaranteeing Western standard processing and quality controls and minimizing the problems of inconsistent sourcing of raw material (this trend also greatly affected the traders and processors located at ports in Europe, who were used to handling and treating imports of crude material from China before distributing to customers). The emergence of Western minerals inspection companies allowed to operate independently in China also greatly facilitated the increase in quality of China's mineral exports. China's central government also introduced controls on export prices and volumes, which had an immediate and lasting effect on minerals trade from China.

By the start of the new millennium, China's economy was starting to take off. Private mining enterprises were allowed to flourish, Chinese minerals producers (and end-product manufacturers) were operating with imported technology and equipment, overseas companies could run wholly owned operations in China, foreign investment increased, and the China trading outpost of Hong Kong became redundant as Shanghai, Dalian, Tianjin, Zhangjian, and Qingdao became the trading hubs of modern China and welcomed overseas businesses.

The result was that Chinese minerals supply increased in quality as well as quantity, and Western minerals producers were now being squeezed out. This was no better exemplified than in the magnesite market, where Western and East Asian refractory producers were able to substitute Western high-purity, dead-burned magnesite supplied with lower-cost fused magnesite from China. This caused Western producers to rethink their grade portfolios and prompted the exit of some big names in magnesite (and fused alumina) in the West and in Japan. China was all dominant.

In early 2005, China's economy was growing at 9.5% per annum (in spite of efforts to cool it down). But in 2003–2004, China's soaring market growth triggered a major shift in world minerals trade. Although China will remain an important exporter of industrial minerals, its ravenous domestic consuming markets became the priority for China's minerals producers. The incentive to export raw material became less attractive (and was replaced by the incentive to export lower-cost finished products such as refractories and ceramics). In fact, the Chinese government took formal steps to conserve its mineral resources, such as reducing mineral export volumes. This prompted a major shortage of Chinese-sourced minerals worldwide. High domestic market demand, limited energy sources, and rising costs, plus a creaking internal freight network, all contributed to a major increase in Chinese minerals prices. As a result of this, Western minerals producers became very much in demand to fill the gap left by Chinese suppliers, and the pattern of mine-to-market supply swung yet again.

Elsewhere, other regions of market growth include central and eastern Europe, where former Eastern Bloc countries and former Soviet Union republics are stabilizing their economies and developing industry and infrastructure. These countries are new targets for

Table 5. Industrial minerals incurring European Commission (EC) antidumping duties, 1996–2005

Mineral	Origin	EC Duty*	Imposed	Expiration Date
Dead burned magnesite	China	Min. CIF € 120 ADV† 63.3%	February 2000	January 2005
Caustic calcined magnesite	China	Min. CIF 112 ADV 27.1%	August 1999	July 2004
Fused alumina	China	Min. CIF € 204	October 1997	October 2002

* Prices in euros per ton; when a minimum price is stipulated, this indicates that the antidumping duty has been determined as the difference between this minimum price of the mineral (as stipulated by the EC) and the net free-at-EU-frontier price of imported mineral from country of origin.

† ADV = ad valorem duty expressed as a percentage duty.

industrial minerals supply and in certain cases hosts to new mineral sources themselves.

Government Trade Policies

A major influence in trade is the role of national governments, which continually strive to encourage investment in their economy and defend their industries from unfair trade practices. A number of particular issues have directly affected industrial minerals trade.

Antidumping Duties

Perhaps the issue most frequently mentioned in terms of trade practice and government influence is *dumping*, which refers to the practice of selling goods overseas (exports) below their normal market value or below the price charged for the same goods in the domestic market of the exporting country. Dumping can be a predatory trade practice whereby the international market, or a certain national market, is flooded with dumped goods to force competitors out of the market and establish a monopoly position.

Reactions to dumping by the importing government can include government subsidies to the threatened domestic industry to temporarily help absorb the losses caused—although this can lead to friction among trade partners. Dumping and predation are considered to be unfair trade practices and, as such, are prohibited under many national trade laws. Although there are variations on this theme, the most common antidumping measure is an added import duty (an antidumping duty) calculated to offset the dumping margin, that is, the discrepancy between home market price (importer's market) and the export price.

Regarding industrial minerals trade, China has been at the center of many dumping issues involving magnesite, fluorspar, silicon carbide, fused alumina, barium carbonate, and titanium dioxide pigment (and, more recently, mineral end products such as magnesia-carbon refractory bricks) exported to European Union (EU) countries, the United States, and the Republic of Korea. Other

countries accused of dumping minerals are Russia and Ukraine for silicon carbide. Table 5 summarizes EU antidumping measures that were in place in early 2005.

India has been the target of dumping for many minerals; those from China include borates, soda ash, fused magnesite, barium carbonate, strontium carbonate, and hydrofluoric acid. In 2003, India instigated antidumping duties on borates from Turkey.

Dumping issues normally take several months to a year to resolve (and longer in some cases), involving investigation by the importing country or trade coalition (e.g., the EC for EU countries) in response to a filed complaint from one or more members of an industry sector (e.g., magnesite producers of Europe, or fused alumina producers of the United States, or a trade association representing its members). The allegation is investigated, including visits to the sources of the exports; a similar market in an unconnected third country may also be evaluated as an example of a typical market for reference; and all parties concerned have an opportunity to comment by a given deadline. A decision is then made to establish if an industry has been materially injured and, if so, what measures should be taken and when. These are then implemented and reviewed, normally after 5 years. The main types of antidumping duties and tariffs can be summarized as follows:

- *Countervailing duty* differs from antidumping duty because it is applied in situations where foreign governments subsidize their industries by providing financial assistance to benefit the production, manufacture, or export of goods. These subsidies can take many forms, such as direct cash payments, credits against taxes, and loans at terms that do not reflect market conditions. Most trade anti-dumping determination bodies have standards for determining when an unfair subsidy has been conferred. The amount of subsidies the foreign producer receives from the government is the basis for the subsidy rate by which the subsidy is offset, or "countervailed," through higher import duties.

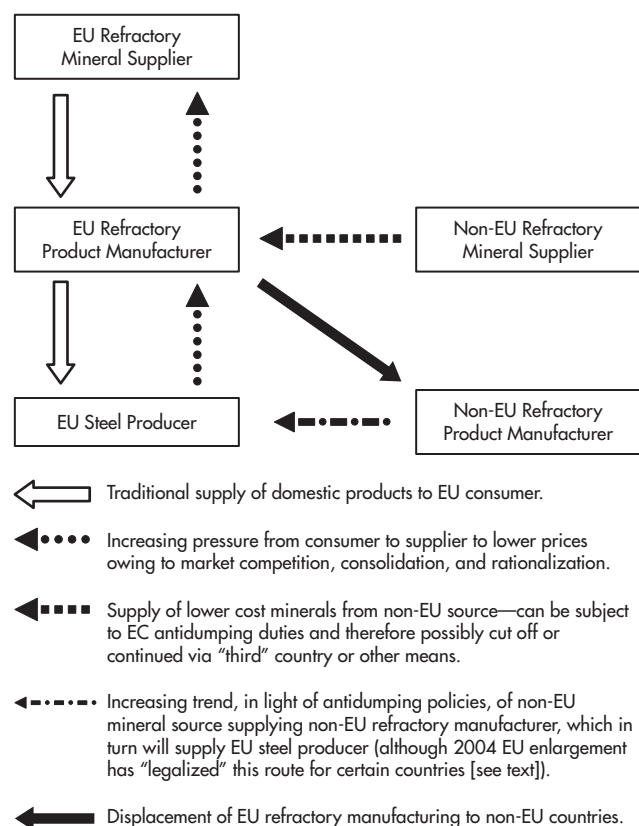

Figure 3. Interrelationships among supplier and consumer in EU refractories sector and influence of EC antidumping policies

- *Minimum import price (MIP)* is one type of antidumping measure. It has drawbacks, however, because it can become irrelevant if across-the-board prices for a particular product area decrease or increase significantly. In addition, it can be bypassed or circumvented through agreements between related exporters and importers, where the exporter supplies the product at an inflated price above or equal to the MIP, then makes the discount after clearing customs. Circumvention can also occur through exporting via a third country to change the country of origin. There are various ways to correct this, and in 2003, the EC altered its policy on an MIP applied to Chinese magnesite imports to the EU because of these types of problems.
- *Ad valorem duty* is the most common form of antidumping duty and is based on the dumping margin, being imposed as either a percentage equal to the dumping margin or a percentage equal to the proportion of the dumping margin that is causing injury. It is imposed as that percentage of the landed price.
- *Tariffs* are completely different to antidumping duties in that they are customs duties that are applied independently, and antidumping duties are applied in addition to any existing tariffs. They are either safeguards against imports that are in such increased quantities to cause or threaten to cause serious injury to domestic producers or simply a means of the home government to raise fiscal revenue. Thus, they do not depend on dumping having been established and do not necessarily apply to a specific exporting country.

Dumping issues are perhaps the most contentious of all mineral trade issues. Basic business rules dictate that as long as there is a free market, there will always be a customer for low-cost goods. Moreover, spurred on by today's increasingly competitive markets, in spite of the best efforts of antidumping policies, it seems there may always be alternative routes for such imports to reach their target market. Unfortunately, the term *free market* may be the subject of debate for some buyers and consumers of minerals. The nub of the debate surrounding the dumping issue has centered on calling into question just who is being protected and whether it is to the greater benefit of the country or region or just for a few threatened producers.

The supply chain involving the European refractories market may be taken as an example that highlights the issues at stake here. Figure 3 illustrates in crude terms the interrelationships between suppliers and consumers, and the influence of EC antidumping policies.

During 2001, the end-consuming market, the steelmaking sector, was facing increased consolidation and rationalization in the EU. As a result, the steel sector imposed intense pressure on refractory manufacturers (and its other suppliers) to lower their prices.

In turn, under pressure to meet the demands of their steel customers, the refractory manufacturers found ways to cut the costs of their raw material purchasing. For example, blast furnace runners are largely composed of silicon carbide (SiC) or brown fused alumina (BFA)—thus, low-cost sources of these materials were sought.

EC antidumping practices, however, instigated to protect the business of EU SiC and BFA producers, cut down the opportunity for EU refractory manufacturers to secure low-cost non-EU supply sources, with no option left but to buy domestic supplies. Furthermore, the European supply market for certain minerals has shrunk dramatically in some cases, such as with BFA and SiC, with just one or two producers remaining in Europe. This has been the upshot of a combination of mergers and strategic withdrawals from these businesses in recent years. Naturally, any EU buyer of these minerals is thus left with little alternative in terms of domestic supply.

Therefore, the policy of antidumping duties on competitive materials outside the EU to protect just one or two producers might start to look a little hard to justify. This is not to say that European producers are taking advantage of the situation, but all the same, this question is being asked more and more.

Two primary consequences have resulted from this situation:

1. Suppliers of low-cost minerals from non-EU sources may be encouraged to find alternative ways of getting their products into the EU market.
2. EU refractory product manufacturing may shift to non-EU countries or be displaced altogether by refractory product supply from non-EU countries that can import low-cost minerals free from antidumping duties and use lower costs of production.

On the first point, certain buyers and traders in the business of sourcing mineral imports will find ways and means, which may be quite legal, to circumvent antidumping policies. Although such practices are nothing new, because of the intense competition in mineral markets today, their implementation over the last few years in particular seems to have grown in frequency and profile.

The most common method seems to be that of routing mineral imports through a third country that is not subject to antidumping duties. Each country has its own set of regulations governing what minimum treatment and enhancement in value an imported product must undergo in order for it to adopt a new country-of-origin label.

As long as traders or mineral suppliers keep within these requirements, there is little to prevent their subsequent export free of anti-dumping duties.

From the consumers' viewpoint this can be an obvious advantage in reopening a source of lower cost material. It may, however, also make it less clear what the original source of the material is, and thus could be subject to possible problems of quality inconsistency if material from different sources is blended without prior knowledge. Examples in recent years have included EU imports of BFA from China via South Africa or Poland, and silicon carbide via Norway, Czech Republic, or Romania.

The second point, that of the threat of increasing production of refractory products from non-EU countries, is indeed a very real concern for the EU refractories sector.

Certain companies have already shifted production facilities to non-EU countries (e.g., Vesuvius International shifting refractory brick production from Whitecross, United Kingdom, to Skawina, Poland). Meanwhile, it is generally considered that the first wave of Chinese refractory raw materials into Europe over the last decade or so is going to be followed by a second wave of low-cost Chinese refractory products, and it is on its way—indeed, in late 2004 the EC was investigating allegations of Chinese MgO-C brick dumping.

So, although some EU minerals producers are being protected from low-cost imports, the manufacturers of the intermediate product (refractories) and the end consumer market (steel) appear to bear the cost of this policy—even though they are trying to eke out a living in the same geographical market (i.e., the EU).

Export Licenses

This initiative is unique to China but has transformed the trade in certain minerals from China to the West. China's central government, through the China Chamber of Commerce of Metals, Minerals & Chemicals Importers & Exporters, implemented its export license system in April 1994. The move was largely to enable stricter control of export volumes and prices, reduce smuggling, and minimize allegations of dumping. Although initially focused on magnesite and fluorspar, by early 2005 export licenses were also required for exports of talc, silicon carbide, bauxite, and brucite.

The concept of the Chinese export license system is generally sound, even if it meant that traders and overseas consumers, having enjoyed relatively low-cost Chinese minerals for a decade or so, now have to accommodate a higher price tag. The problem, however, has been in the administration and subsequent tinkering of the system's rules and regulations on an almost annual basis, and with little or no consistency.

For example, in 2004, bauxite exports were subject to a flat fee of RMB230 (US\$28)/t, but in 2005 the system changed to the notorious bidding and quota system, as used for magnesite exports. In this procedure, suitably qualified parties (i.e., those with a stipulated past record of exporting) bid to secure a limited number of export licenses and volume quotas set for the year's total exports. Officially, those unsuccessful in securing export licenses cannot therefore export, and those that have export licenses but fail to fulfill them are subject to a penalty fee and relinquish their right to bid in the following year.

In reality, an underground market for export licenses develops, and inevitably there is some collusion in bidding among prospective exporters. Concerning magnesite exports, there have been at least five successive versions of an exporters' syndicate since 2000, each with laudable aims but lasting only a few months to a year before breaking up over disagreements on prices and procedures or because of apathy. The magnesite export associations have generally tended to increase the price of exported grades.

Smuggling also has become a problem, with unqualified exporters either doctoring export documents or exporting via "third" ports in China or Republic of Korea. Any smuggled shipments of bauxite or magnesite that are suddenly confiscated or impounded by the Chinese authorities naturally have a major effect on waiting consumers overseas.

A very frustrated and confused trading community has been trying to keep up to date with the continually changing export license system and its disruptive impact on prices and material availability. For 2005, in its efforts to conserve its raw material resources, the Chinese government issued reduced export quotas of certain minerals such as bauxite and increased its prices. Although this disrupts supply of minerals from China, it does give impetus to overseas producers to plug the gap with their products.

Other Taxes

In addition to export taxes, countries can impose so-called resource taxes on certain minerals, and China has implemented this with magnesite mined in Liaoning Province. The resource tax thus adds to the overall price of the mineral and has been approximately US\$10 to \$40/t.

Removal and reduction of tax rebates on mineral exports is another issue that has ramifications in world minerals trade. In October 2003, China announced reductions or cancellations of a range of mineral exports, including bauxite, silicon carbide, BFA, magnesite, fluorspar, talc, rare earths, graphite, and barite. Rebates ranging from 13% to 17% were cancelled or reduced to 5%. For most mineral exporters, this resulted in at least a \$2/t increase in prices.

Trade Bans

One obvious measure that has a direct effect on minerals trade is any government or intergovernmental ban on trade in a particular mineral. Perhaps unsurprisingly, asbestos has been the mineral whose trade has been most affected in this way. Trade in asbestos-containing products has already been curbed between most developed countries, and in late 2003, an intergovernmental committee agreed that the four asbestos minerals—amosite, actinolite, anthophyllite, and tremolite—should be added to the Rotterdam Convention Prior Informed Consent (PIC) list. In 2004, however, leading asbestos-producing countries such as Canada, Brazil, Russia, China, and Zimbabwe successfully challenged the addition of the asbestos mineral chrysotile to the PIC list.

Initiated in the 1980s, the voluntary PIC procedure required exporters trading in a list of hazardous substances (such as asbestos) to obtain the prior informed consent of importers before proceeding with the trade. In 1998, governments decided to strengthen the procedure by adopting the Rotterdam Convention, which makes PIC legally binding.

It is likely, however, that chrysotile will eventually meet the same fate as that of the other asbestos minerals, and asbestos mineral trade will cease altogether. In late 2004, Canada's largest chrysotile producer, LAB Chrysotile, indefinitely shut its Black Lake mine near Thetford Mines, Quebec. Among other reasons, the company cited exaggerated standards set by the provincial health and safety board, and numerous studies about the dangers of asbestos, as issues that prompted its decision to close the mine.

Trade Agreements

In contrast to trade bans, there are intergovernmental initiatives on international trade that can greatly enhance minerals trade. There are basically three levels of international trade agreements: bilateral relationships (e.g., Canada–United States Free Trade Agreement); multilateral arrangements (General Agreement on Tariffs and Trade

[GATT] and the World Trade Organization [WTO]); and regional agreements (North American Free Trade Agreement [NAFTA], Southern Cone Common Market [Mercado Comun del Cono Sur, or MERCOSUR], Caribbean Community and Common Market [CARICOM], and ASEAN Free Trade Area [AFTA]). Each aims to generally improve and facilitate trade among countries signed up for the agreement and normally will assist international trade in industrial minerals. The proliferation of regional trade agreements has been instrumental in changing the framework of world trade; more than one third of global trade takes place between countries that have some form of reciprocal regional trade agreement.

Two of the most significant developments in recent years include China's accession to the WTO and the enlargement of the EU. By 2005, the full impact of China's recent admission to the WTO remained to be seen, but one of the main ramifications of WTO membership for China will be its having to adopt WTO rules and regulations and the effect of this on China's current trading practices. For example, WTO membership might now signal the end of the mineral export license system that China initiated in 1994, which may have a profound effect on trade in certain minerals.

At midnight on April 30, 2004, the EU formally accepted 10 new member states into its fold: Cyprus, Czech Republic, Estonia, Hungary, Latvia, Lithuania, Malta, Poland, Slovakia, and Slovenia. Enlargement Day on May 1, 2004, concluded several years of tough negotiations and is one of the most important opportunities for the EU at the beginning of the 21st century. Significantly for industrial minerals trade and markets, enlargement has increased the EU's aggregate population from 378 million to 450 million—second only to China and India—and 160 million more than that of the United States.

With regard to the effect on industrial minerals, there are several issues to keep track of:

1. Expanded markets: An enlarged population equals expanded markets for industrial minerals in general.
2. Demand for modern products: Certain countries' markets are demanding Western standard manufactured products; this will drive existing EU minerals producers to supply them and prompt new member-state producers to develop and supply required grades to manufacturing plants.
3. New sources developed: The potential exists to develop new mineral deposits within new member states to supply EU markets, with possible reduction of reliance on imports.
4. Shift in manufacturing: Potential increase in shift of manufacturing plants to areas of cheaper labor could in turn influence development of mineral deposits, supply bases, and EU trade.

Clearly, for countries like the Czech Republic, Slovakia, Slovenia, Hungary, and Poland, accession to the EU has lifted any anti-dumping duties and other tariffs previously legislated against them by the EU and will be welcome by mineral suppliers of those countries (but perhaps not by those of other EU countries). Another factor that will influence trade relations is that many of the accession countries retain strong industrial links with Commonwealth of Independent States (CIS) countries, particularly Russia and Ukraine. These relationships should work to the advantage of the EU by strengthening or opening up new trading links among the existing EU-15 and the CIS.

Shipping and Freight Rates

The influence of shipping and freight rates on global trade and prices for industrial minerals cannot be overstressed. One of the most frequently cited reasons for producers and traders increasing

raw material prices is cost of freight, along with rising energy prices. Changes in the global freight market can have a profound effect on minerals trade, and this was starkly illustrated by events in late 2003, when a turnaround in global freight conditions hit the market with particular severity.

The freight market in 2002 witnessed such historical lows that almost every transport user within most commodity groups, shipping providers, and even shipbrokers had no inkling as to the severity of change that was to occur in 2003, which would have ramifications for the next few years. The significance of the turnaround lies in the phenomenal price increases experienced in every sector of the dry cargo market during the second half of 2003.

Usually, buyers and sellers of higher-valued commodities have not worried greatly about the movements within the freight market, because these changes represented a small percentage of the delivered price (unlike for industrial minerals). The freight market appreciation in 2003 changed all this because low-value inputs were especially affected (i.e., such as industrial minerals). Producers seeking to maintain market share in an oversupplied market are at the mercy of these changes unless the buyer is prepared to accept the gravity of change and reflect this in the price. Now, more than ever, low-value commodity suppliers such as mineral exporters are selling freight.

The key drivers of the freight market's strength included:

- Massive demand for raw materials in China (the country recorded record imports of grain, coal, iron ore, and steel)
- An upturn in key global economies (Organisation for Economic Co-Operation and Development [OECD] 5%, Europe 1.8%, Japan 1.8%, United States 3%, and India 6% to 7%)
- Slowdown in fleet regeneration
- Increased regional trade (stemming from the Asian crisis, growing interdependence, and more efficient employment of shipping)
- Surge demand (resulting from unforeseen demand bubbles)
- Port congestion

All these factors contributed to what many have considered to be the most significant shift ever in the bulk shipping market (container rates were also affected). Mainly because of a shortage of vessels and soaring demand for raw materials in China, freight rates almost doubled in just 1 month in late 2003. The effect was increased pricing for a number of key industrial minerals, including barite, bauxite, fluorspar, magnesite, and zircon. For example, Chinese barite prices (CIF U.S. Gulf Coast) rose to US\$62.50 to \$64.50/t from US\$42 to \$47/t. Also, because of congestion at ports, the cost of demurrage (the extra charge levied by shipowners as compensation for delays in loading/discharge) rose sharply.

The degree of change and the influence of huge demand for raw materials to feed Chinese growth have made suppliers reexamine the profitability of competing in distant markets where freight has the propensity to erode profitability. Similarly, consumers are reexamining their usual sourcing of product to reduce their delivered costs. These changes may result in a realignment of trades (as consumers source minerals from elsewhere to reduce shipping costs) or simply a reduction in the dependence on bulk shipping and increased usage of containers as a mode of transport because of their competitive pricing.

In 2004 and 2005, the container market witnessed a massive increase in capacity with new and larger container vessels on order. The container lines will want to fill the slots and acquire the economies of scale demanded by the new generation of large container-capacity vessels (some 4,100 teu [20-ft equivalent unit] compared

to the existing fleet average of 1,900 teu). By late 2004, certain bulk trade routes had become so expensive that containers had been able to capture certain commodity trades that logically should have been conducted onboard Handysize or Panamax vessels.

The changes will stimulate a reexamination of key elements within the supply chain, including:

- The freight economics of variable tonnages
- Storage—the ability to handle larger volumes and attract economies of scale
- Production scheduling

A classic example of the influence of a combination of freight and tax factors on the barite market took place in mid-2004. Rising prices for Chinese drilling-grade barite as a result of high ocean freight rates, Chinese port congestion, hampered overland logistics, and the lowering of the value-added-tax (VAT) rebate on barite exports from China enabled barite sourced from Nevada to be competitive again in the Gulf of Mexico drilling mud market. It became much more expensive and time consuming to get Chinese barite to key ports because trucks that previously carried 30 t were limited, almost overnight, to 20 t after a government crackdown on overloading. In many cases, this one factor increased the cost of getting material to the port by 10% or more.

This had the effect of prompting key Gulf consumers to look at renewed investment at their Nevada barite mine and grinding plant operations. The long period of dominance by imported Chinese barite in the Gulf of Mexico market began in the mid-1980s, when the domestic mining operations in Nevada were cut back from their 1982–1983 peak production of 5–6 million tpy to 1.5–2 million tpy, which is where they have stayed to date. Until mid-2004, the cost of shipping barite from Nevada to the southeastern United States by rail had simply priced it out of the Gulf market, and, incredibly, it was more economical to ship barite from China. This 20-year status quo is now changing, however, and the Gulf of Mexico drilling market will be seeing an increase in supply of barite from Nevada, a weakening of dominance from Chinese imports, and perhaps a rejuvenation of supply from other sources such as India and Morocco, which had also been priced out by the Chinese.

OUTLOOK

World trade growth averaged 10.2% in 2004, reflecting rapid increases in industrial production and investment activity. More than 20% of the increase in world trade volumes was accounted for by China, whose imports increased by 30% in 2004. Although China's growth economy will slacken off somewhat, the country is expected to remain a strengthening powerhouse in the overall growth region of East Asia at least until 2010. Overall, world trade was expected to slow slightly to 8.5% growth in 2005.

Industrial minerals trade patterns will continue to react to the performance of the leading world economies and the global freight market. The developing markets in China, East Asia, and eastern and central Europe will continue to attract minerals trade as they grow. In time and with continuing overseas investment, these regions may develop their own mineral sources that will join the world export market.

The Middle East region has very good prospects for attracting increasing minerals supply, but continuing conflict and political uncertainty will naturally stifle any rapid growth in this region for the time being. Perhaps the great unknown market and trade influence in waiting is Russia. At present, much of Russia's supply and demand of minerals is contained within this huge country. As Russian demand for superior end products grows and its manufacturing technology develops, however, increased overseas interest and investment may open markets for imports and even unlock mineral sources for export.

Applying Industrial Marketing Concepts to Industrial Minerals

Todd Harris

Industrial products such as industrial minerals are for the most part distinctly different from those that consumers purchase for their own uses. It follows, then, that industrial marketing—which involves marketing industrial goods and services to commercial enterprises, governments, and other non-profit institutions for resale to industrial customers, or for use in goods and services that they produce—is also different from consumer goods marketing. The distinction is that the latter involves the marketing of goods and services to individuals and families for personal consumption and to wholesalers and retailers in the distribution system. The key to industrial minerals marketing is identifying the intended customer and the nature of that customer. This gives rise to different challenges and approaches in understanding and applying marketing concepts to industrial minerals. Table 1 illustrates some of these challenges in industrial marketing research compared to consumer marketing research.

CLASSIFICATION OF INDUSTRIAL MINERALS

Basically, all industrial minerals can be classified by their use or performance as either chemical or physical minerals. These classifications are simplistic but often determine how a product is marketed: as a commodity that is sold on price or as a specialty product or material sold on performance in its use. Chemical products are those employed primarily as sources of specific chemical elements or compounds. Five basic end uses consume almost all chemical minerals, as shown in Table 2. A major use of these minerals is as chemical raw materials. Such minerals as salt, lime, soda ash, and fluorspar are primary sources of chlorine, calcium, sodium, or fluorine.

An even larger category is fertilizer raw materials, of which phosphates, sulfur, and potash represent more than 90% of demand. A smaller category is chemical process aids, primarily water treatment minerals such as salt, lime, and caustic soda. Another smaller category is ceramic raw materials, most notably industrial sand, soda ash, and fire clay. The basic characteristic of all these chemical minerals is that they are marketed on chemical content and specifications of purity. As a result, they tend to be more like commodities, with similar products available from several sources at comparable prices. Minerals used for metallurgical fluxes are an example.

Physical minerals, the other major classification, are products sold to performance specifications, mainly for their ability to enhance the value and properties of the end product and not as much for their composition (although chemical compatibility with the end-use product is essential). Similar to chemical minerals,

Table 1. Characteristics of industrial versus consumer marketing research

Key Element	Industrial	Consumer
Sample size	Small	Large
Sampling method	Selective for largest consumers 80/20 rule	Random sample
Sample type	Consumers, competitors, government, other factors	Consumers only
Data processing	Computer-based but often unstructured	Highly structured, using statistical analysis software
Statistical significance	Low due to small sample sizes	High
Cross-checking against other factors	Extensive	Little or none
Key factors	Based on expert judgment	Based on statistical selection techniques

Table 2. Major types of chemical industrial minerals

Market Segment	Major Minerals
Chemical raw materials	Salt, phosphates, soda ash, sulfur
Fertilizer raw materials	Phosphates, sulfur, potash
Chemical process aids	Salt, lime, salt cake
Ceramic raw materials	Sand, soda ash, fire clay
Metallurgical fluxes	Lime, sulfur, fluorspar

Table 3. Major types of physical industrial minerals

Market Segment	Major Minerals
Structural minerals	Sand and gravel, crushed stone
Performance minerals	Kaolin, calcium carbonate, talc, mica
Process aids and absorbents	Attapulgite, bentonite, barites, diatomite
Foundry minerals	Industrial sand, bentonite, zircon

these physical minerals have several basic end-use markets, as shown in Table 3. Important mineral properties required in these applications are brightness, particle size, particle shape, specific gravity, hardness, color, absorption characteristics (e.g., ranging from absorption of polymer resins to various fluids), and electrical

Table 4. Business characteristics of various types of industrial minerals

Characteristic	Chemical Minerals			Physical Minerals		
	Chemical Raw Materials	Fertilizer Raw Materials	Ceramic Raw Materials	Performance Minerals	Structural Minerals	Absorbents/Process Aids
Cyclicality	High/Large	High/Large	High/Large	Low/Small	High/Large	Medium/Moderate
Company size	High/Large	High/Large	Medium/Moderate	Medium/Moderate	Medium/Moderate	Medium/Moderate
Number of customers	Medium/Moderate	High/Large	High/Large	High/Large	High/Large	Medium/Moderate
Captive production	High/Large	High/Large	High/Large	Low/Small	Low/Small	Medium/Moderate
Technical service	Low/Small	Low/Small	Low/Small	High/Large	Low/Small	Medium/Moderate
Capital intensity	High/Large	High/Large	Low/Small	Medium/Moderate	Low/Small	Medium/Moderate
Research and development	Low/Small	Low/Small	Low/Small	Medium/Moderate	Low/Small	Low/Small
Marketing intensity	Low/Small	Medium/Moderate	Low/Small	High/Large	Low/Small	Medium/Moderate

conductivity. Except for structural minerals (e.g., construction materials), virtually all categories of physical minerals are smaller markets than those listed under chemical minerals.

Structural minerals are the largest subgroup in the physical minerals category. Sand and gravel and crushed stone are the major products in this market segment. Although sold to specific performance specifications (e.g., American Society for Testing and Materials, U.S. Department of Transportation), the markets for these materials tend to be defined regionally because of their low unit value and broad availability. In addition, because of their volume, structural minerals often are considered a separate segment of the industrial minerals industry.

Performance minerals are the largest segment in terms of the number of different products available, with roughly 15 major sub-product categories. This is the group that often is associated with the use of marketing practices in industrial minerals businesses because of the unique nature of how these products perform and are sold. Key products in this segment include kaolin, ground calcium carbonate, and talc.

Process aids and absorbents are minerals primarily used in drilling fluids or as filter aids and suspension aids; but they also include such end uses as iron-ore pelletizing and animal litter. Consequently, minerals such as attapulgite, bentonite, barite, diatomite, and perlite are the major types of products sold in these markets. Foundry minerals include products such as industrial sand, bentonite, and zircon used in castings and parts for the automotive and aerospace industries. Table 4 gives a comparison of business characteristics of various types of chemical minerals and physical minerals.

If one accepts the notion that specialty businesses are relatively small in volume but with high value added and good growth potential, then such physical mineral businesses as performance minerals, process aids, and absorbents are the most specialized and attractive of industrial minerals from a marketing perspective. Conversely, chemical and fertilizer raw materials, owing to their large market size and relatively low historical growth, are most like commodities and therefore least likely to benefit from added marketing other than to promote the beneficial nature of these materials as part of a consumer awareness campaign.

ADDING VALUE TO INDUSTRIAL MINERALS

Added value is a term often associated with certain classes of industrial minerals. But what does it take to provide a value-added product and, equally important, how does a producer obtain the value it delivers to its customers? Most companies mistakenly look at the value-added portion of a product from a cost-plus perspective, that is, the price that can be obtained above the production cost for that

material. This approach, however, does not ensure that a product can be produced or maintained profitably. It is important to understand how to produce a value-added product, but it is equally important to appreciate how market forces can affect the value added. Four factors generally influence added-value opportunities for industrial minerals: the mineral deposit, the processing method, marketing and market price, and competition.

The Mineral Deposit

All opportunities to add value to an industrial mineral begin with the deposit. The geologic environment determines the physical and chemical characteristics of a mineral, which in turn determine the extent that value can be added to it. If a deposit can yield unique products for specialty applications, then the location of that deposit relative to its market is less critical; if, however, a deposit can be used only to produce commodity grades, then production cost and proximity to market are more critical.

Calcium carbonate is a prime example of how quality and location of a deposit can affect a company's ability to add value to its products. Limestone, or calcium carbonate, is one of the most widely occurring industrial minerals in North America, yet only a few high-quality (typically defined as high brightness) deposits are mined at present. The natural whiteness or brightness of calcium carbonate from these deposits gives producers a unique advantage for such color-critical markets as paper, paint, sealants, and plastics.

Processing Method

The second factor to consider in developing a value-added material is the processing method employed. If a mineral has the essential geologic characteristics and can be mined economically, then the next step to adding value is through processing techniques such as crushing, grinding, separation, classification, and surface treatment, as illustrated in Figure 1. The degree of processing will increase the production cost of the material as well as the value of the material, but not always in direct proportion. Reducing the particle size of a mineral is the most common way to derive additional value, but for certain performance industrial minerals, including calcium carbonate, adhering to strict physical parameters such as particle size, shape, and distribution is equally important. These products may also have fairly rigorous chemical or color specifications in addition to physical sizing requirements. The form in which the product is delivered (e.g., slurried, densified, pelletized), the package size, and method of delivery also can contribute greatly to the value-added benefit of the material to the consumer. In many cases, through unique or proprietary processing and delivery systems, suppliers tailor their products to specific customers and end uses to derive the added value.

Figure 1. Relative value-added contribution from the processing of industrial minerals, by stage (unshaded portions of bars represent potential ranges of value that can be obtained from each process)

Marketing and Market Price

The industries purchasing and using these products are diverse, and each has its own specification requirements. In general, however, there is some compatibility among customers within specific industry classifications. For example, paint, plastics, and rubber applications may all use a 3.0- μm ground calcium carbonate product, but raw material specifications for all three industries may be different on several specific chemical or physical parameters. Furthermore, within a given industry group, individual customers' sensitivities relative to specification tolerances and variations from mean datum points can be significantly different (Freas 2002).

The capacity to derive added value from a product often is determined by the market price that a firm can obtain for that material. The market price depends on the supplier's ability to price the product on its value to the customer or end-use product, not the cost to produce it. An important marketing factor that affects a company's ability to price for value is product differentiation. "Sales and service" is one of the key marketing tools commonly used to add value and differentiate a product from competitive offerings. Such techniques include improving packaging and handling, offering application data and other technical information, advertising, and providing reliable and knowledgeable technical service and support. Sales and service is only one aspect of marketing. Marketing value-added industrial minerals involves a strong commitment to research and development and corporate support from the start, followed by the combined efforts of technical service, quality control, sales, and customer service staff. The supplier must be able to demonstrate its products' benefits and unique qualities, and then ensure support for those products. All this rarely is achieved overnight. Companies successful at developing value-added industrial minerals—for example, Nyco Minerals (wollastonite) and Suzorite/Zemex (mica)—spent years researching and developing their product offerings for plastics and other markets before any significant sales were realized.

Competition

Market competition is the other critical factor in the value-added equation. Companies must be innovative in their product development efforts to add value to their products but also stay ahead of their competitors, or the "me too" suppliers. Competition from these in-kind suppliers, and from substitute products, is what ultimately leads to lower prices, reduced profitability, and the subsequent erosion of value added. Suppliers that have the benefits of a quality raw material resource, a unique and cost-efficient process-

ing technology, and a reliable sales and R&D capability occupy the best position to withstand any threats from these competitors.

BUILDING AN INDUSTRIAL MARKETING STRATEGY

The key variables in any marketing scheme include (1) product planning/positioning, (2) pricing, (3) distribution, (4) advertising and promotion, and (5) customer relations and sales. Depending on the nature of the product, the market, and the competition, there may be many other strategic variables such as resource and plant locations, technical service, customer service, and sales schemes. Strategic planning involves making choices in each of these areas and in allocating resources—labor, capital, physical assets—to such elements of the marketing program as new product development, field sales, advertising, and inventories.

In general, suppliers commit more resources proportionally to field sales and technical service elements in an industrial marketing campaign than to media and print advertising when compared to a consumer-goods marketing campaign. This is because industrial customers for any given product, whether an industrial mineral or a piece of equipment, often (but not always) are small in number, readily identifiable, and reached directly and personally more economically. Another consideration is the nature of communications required. Industrial customers may need technical education in the use or application of the product, and sometimes the performance and benefits of that product in the customer's final product. In addition, suppliers need continuous and detailed feedback from their customers on any problems dealing with product quality and performance in order to troubleshoot and also to offer new product innovations.

Product Planning/Positioning

Industrial goods producers often face basic decisions regarding where in the supply chain they want to position themselves and their products. Do they want to function as a raw material supplier, a supplier of components or semifinished products (e.g., masterbatches), an end-product supplier, or all three? Pulp and paper companies, for example, often function as suppliers of pulp and timber, paper and wood products, and converted products. The manufacturer who operates at more than one level in the supply chain is often said to be "competing with its customers." Although this is not entirely an undesirable position, and in some cases can lead to faster market penetration, it does introduce certain conflicts of interest in strategic planning between one market level and another. Efforts to strengthen a position in one sector can sometimes adversely affect marketing efforts in another sector.

Pricing

Pricing conventions used in industrial marketing also distinguish this field from consumer goods marketing. For example, competitive bidding is widely used in industrial marketing on large equipment and raw material supply orders. Paper companies often will bundle their purchasing requirements from several plant locations to maximize their purchasing leverage. Bids often are based on specifications issued by the purchaser, and, in a strict situation (often with government agencies), may be opened publicly and awarded to the lowest qualified bidder. More often the initial bid may serve only to narrow the field of potential suppliers, and negotiations between competing sellers and prospective buyers may proceed from there.

It follows that many contracts for industrial goods are priced individually. Except for commodity products (e.g., chemical raw materials), which are relatively undifferentiated among different suppliers, orders for industrial goods have unique specifications, delivery terms, and quality requirements, with pricing on an order-by-order

basis. This poses some problems for the marketing of the industrial products in both cost calculations and the value to the end user, and also in the determination of competitors' prices.

On many standard items, list prices are a starting point, with discounts offered for the size of the order and class of customer (e.g., distributor, end user) and with extras or markups for special packaging and freight options. Price negotiation is an important part of the industrial buying and selling process. In each case, the relative skill and purchasing power of large and small industrial customers are taken into account when dealing in the free market environment.

Distribution

Characteristically, conflicts may arise when industrial goods manufacturers have to sell to both a few very large customers and many relatively small accounts. This is particularly true in market segments such as the paint and plastics industries. It is typically more economical for a supplier to sell directly to a large buyer. In addition, most companies have key account programs that focus on selling to large buyers both for strategic reasons and to build strong customer relationships. Small buyers are served more efficiently through agents or distributors that carry a larger mix of smaller volumes to supply these customers with less-than-truckload (LTL) quantities and offer faster delivery as necessary. Because some small accounts eventually become large accounts, and because legal issues prevent most suppliers from exercising domain over all the accounts a distributor solicits, suppliers and distributors often find themselves competing with one another at various times for the larger accounts.

The basic problem (or opportunity, depending on one's perspective) stems from the fact that most markets are in a constant state of flux with growth likely to occur. A distribution system for one stage of market development may not be appropriate at another stage. In addition, the system planned for one market segment may not be effective in another, say, where the buying practices and the size and number of customer accounts are different. Company-owned and -operated distribution systems can be effective in certain sectors but often require large, fixed cost or capital commitments (e.g., warehousing, transportation, inventory) that cannot be changed easily or adapted to shifting market conditions.

Advertising and Promotion

Although media or print advertising plays a smaller role in industrial marketing than in consumer goods marketing, it can contribute in the development of a new product or market when it creates a favorable image with potential buyers and the general public. In addition, the right use of advertising can create a favorable environment for the company's field sales representatives, in their direct dealings with potential buyers and customers, and at industry conferences and trade shows. Industrial marketers increasingly use advertising to create product "pull through" by directing their message at the end user to whom the product ultimately is sold. Building stone manufacturers, for example, have long promoted the beauty and durability of their product through architectural publications, encouraging architects to specify these products in their building designs. The purpose of this approach often is to develop brand recognition with the end user (in this case, the architect or commercial real estate developer) to influence them in the choice of materials that contractors will use. One of the most prominent campaigns developed by an industrial marketer to promote its material to the end user was by BASF, which popularized the slogan, "We don't make a lot of the things you buy, we make a lot of the things you buy better." This campaign successfully created end-user

recognition for its functional polymers. Similar advertising strategies ultimately aim to build stronger competitive positions and stronger relations with key customer accounts.

Customer Relations and Sales

In industrial marketing, buyer/seller relationships tend to be both continuous and complex. They often go well beyond sales transactions and very often involve technical assistance to customers, joint product development efforts, and product service. Advertising on behalf of customers, financing their purchases, and entertaining key managers in customer companies are tactics intended to put sellers in a favorable competitive position. Alliances or customer partnerships also may be formed as part of the buyer/seller relationship. This often involves mutual supply and purchase agreements where either party benefits from a product that the other produces or in some cases where one's by-product can be used by the other party. An example of this type of relationship is in the fumed silica (a reinforcing material used in silicone rubber compounds) industry, where the fumed silica operator supplies a by-product acid such as hydrochloric acid to a neighboring silicone rubber producer, who in turn supplies the fumed silica producer with a chlorosilane feedstock (a critical raw material) from the latter's production process. In general, developing such a strong mutual working relationship with one's customer is pivotal to industrial marketing success.

MARKET SEGMENTATION SCHEMES

Market segmentation schemes are an important part of a market plan designed to sort customers into homogeneous groups according to their purchasing practices and product applications. This type of approach provides the essential framework within which marketing strategies focus on the needs of different market segments.

There are at least four ways of segmenting industrial markets like industrial minerals. The first is by product. A kaolin manufacturer might group his customers in terms of the products they buy—filler, delaminated, engineered, calcined. Market segmentation by product is especially helpful if products are highly differentiated technically and where conveying product knowledge to customers is a critical dimension of selling.

The second scheme is by end-use application. Again, using the kaolin manufacturer example, this type of supplier might segment its markets into groupings such as ceramic, paper, and specialty (e.g., paint, rubber, plastics). This segmentation distinguishes customers by the way each uses kaolin and the type of delivery system that each typically requires. This approach can vary greatly from one customer grouping to another. The most critical aspect of selling is to understand the customer's business and the way the product (in this case, kaolin) serves the customer's needs. The set types of classification schemes also are important in promoting manufacturing facilities in an efficient manner to meet various grade requirements of end-use industries and customers.

The third segmentation scheme is to classify by geography. This scheme recognizes the broadly diverse character of market environments worldwide. Marketing industrial minerals to food and healthcare markets in Europe, for example, requires adhering to different standards than those promulgated in the United States or elsewhere in the world. The differences may arise from government controls, monetary conditions, and the wide variations in marketing and supply infrastructures (agents, distribution terminals, etc.). Under these circumstances, coping effectively with the local market environment may be the critical dimension of successful market development.

Finally, markets can be segmented by the way its customers buy. Government agencies buy products and services differently

than commercial enterprises do. As mentioned, government agencies typically require that suppliers submit bids and, depending on the product, a number of different people may be involved in the buying decision. Large companies buy differently than small companies do: large companies often employ more structured purchasing procedures than do smaller companies and are characteristically more price sensitive.

Which scheme for classifying industrial customers is appropriate for each business enterprise will vary from one industrial market to another. Moreover, the scheme that may be appropriate at one stage of market development may be outmoded at another. In general, segmenting the market by product is useful in the early stages when customers need product education; the most essential factor in competitive effectiveness is technical product knowledge and the ability to communicate it to one's customers. In the later stages of market development, a segmentation scheme by product tends to evolve into segmentation by end-use application, when product uses have been identified and product knowledge has advanced to the point that much can be systematized by type of application. At this stage, competitive strength in the market is based on understanding the technical aspects of the customer's business and of the use of their product in its production system. In the more mature stages of market development, when customer education in product and application knowledge are no longer primary concerns, and when major competitors are equals in the services that they provide, buyer segmentation schemes tend to

predominate. The critical element in marketing success at this stage, therefore, is knowing the customer's purchasing procedures and the emphasis placed on factors such as price, availability of supply, product consistency, and quality.

Although the timing and appropriateness of geographic segmentation schemes vary by product and supplier, the conventional application of this method tends to be earlier rather than later in market development. This assumption is based on recognizing that markets in different parts of the world become more alike with time for any given product. Common patterns of product use and of government influences on product forms, pricing, and promotion begin to emerge along with the marketing infrastructure. Most suppliers tend to subordinate geographic distinctions in developing a market strategy and employ a framework for strategy based on end-use application and buyer criteria. The purpose in considering market segmentation schemes is primarily to help understand the many possible approaches along which market information may be gathered, customers classified, and strategies developed. For each particular market served, suppliers should have subordinate strategies for individual customers.

Due Diligence and Financial Valuation of Industrial Mineral Assets

Ken Santini, James M. Barker, and Edwin H. Bentzen III

INTRODUCTION

A due diligence investigation of an industrial mineral asset may be requested for multiple reasons. For example, the buyer will require it before taking title or a lender will require it before providing financing. There are also different levels of due diligence. A due diligence investigation of an asset could cover all aspects including reserves, mine, processing plant, environmental issues, markets and sales, and financials, among others. Another investigation could focus on a single issue such as reserves. Due diligence investigations of industrial mineral assets identify risks (failure and impact) and assess the facts and factors related to those risks. The due diligence investigation provides competent backup data for a business decision and must be completed before upper management makes a commitment (Santini and Hammond 2000).

Financial valuation may also be part of the due diligence process. One of the commonly used standards of value is *fair market value*, defined as the cash or cash equivalent price at which property would change hands between a willing buyer and a willing seller, both being adequately informed of the relevant facts and neither being compelled to buy or sell. In assessing an asset's fair market value, the three generally accepted approaches to value—market, income, and cost—can be employed. These approaches are based, respectively, on market exchanges for comparable business interest or assets, the capitalization of income, and the cost to reproduce assets (Santini and Hammond 2000).

No set standard on how to design and complete a due diligence investigation exists (O'Driscoll 1999). Each due diligence team should know the key issues from their perspective and focus on those and perhaps exclude others. The discussion in this chapter, although not all-inclusive, does highlight the complex nature of a due diligence investigation.

Industrial minerals are wide ranging, comprising at least 50 major commodities and thousands of products. Classification of industrial minerals is difficult (Austin 1999), so time should be spent developing an understanding of the industry before venturing forth.

This chapter is presented as an outline because a narrative would be extremely long; each section could be a book on its own. It is not the authors' intention to describe *how* to conduct an investigation, but rather to demonstrate *what* could be investigated for each due diligence case. The outline will aid the due diligence team in ensuring complete coverage. It will also aid management in gauging the specific knowledge needed by the due diligence team.

DUE DILIGENCE INVESTIGATION

A due diligence investigation ranges from the very specific, such as a reserve audit, to a complete audit of all phases of an asset (Santini 1999a, 1999b; Toll 1999).

Due Diligence—What Is It?

- It is a process of evaluating a company or asset from a buyer's perspective and preparing to transition it to new ownership.
- It is a process of preparing a company or asset for sale from the seller's perspective and identifying how and when data should be provided to potential purchasers.

Due Diligence—Why Do It?

- Addresses the basic law of business: caveat emptor
- Risks of the business rest on the buyer
- Representations and warranties in the selling documents can address only a limited number of risks
- Identifies risks and assesses facts and factors related to those risks
- Confirms value and investigates upside potential and synergies
- Provides competent backup data for business decisions
- Required by a lender before funds are released

Due Diligence—Who Does It?

- Company management/employees
- Financial advisors
- Consultants/attorneys/accountants/other specialists
- Type and number of people depend on size of the deal, complexity of the asset, and time available for conducting the investigation

Due Diligence—When Is It Done?

- Typically within a specified time period designated by the seller
- Often in a very limited time period
- After signing of a confidentiality/nondisclosure agreement
- Could involve initial phase before submission of an indicative or qualifying bid
- Should always include a detailed investigative phase prior to closing of the transaction

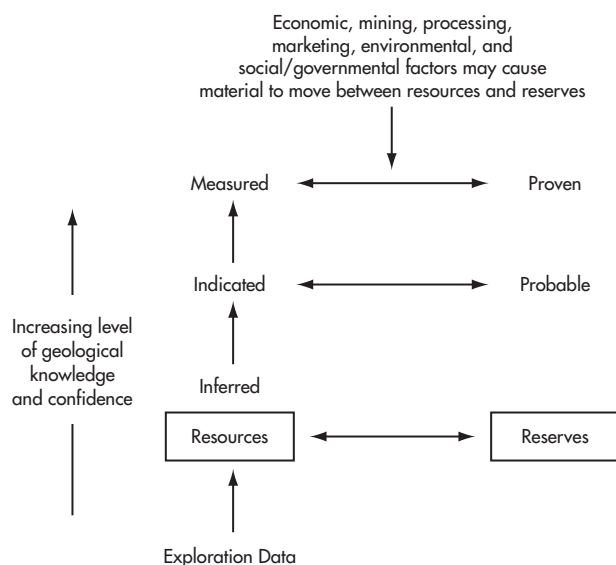

Figure 1. Hierarchy of resource and reserve terms showing relationship among geological knowledge, economics, and other factors. The key point is that resources move into reserves and back to resources depending on nongeologic forces that allow a profit to be made (reserve) or not (resource).

Due Diligence—How Is It Done?

- Visits to data room/seller's office
- Mine/plant/warehouse/terminal site inspections
- Inquiries with regulatory agencies
- Check of court records
- Discussions with suppliers, customers, distributors, agents, seller staff, etc. (if allowed)
- Formal report of findings that includes the following:
 - Proof that assets exist as represented by seller who has the right (title) to sell
 - Identification, description, and assessment of any risks
 - Discussion of strengths and weaknesses of the operation
 - Confirmation of value

Seller's Due Diligence Process—Do's and Don'ts

- Use a financial advisor with expertise in industrial minerals to divest of the asset.
- Have no direct contact with potential purchasers.
- Inform selected company personnel of impending sale.
- Arrange for key personnel to be available during management presentations and data room and site visits.
- Prepare an information memorandum and get a confidentiality/nondisclosure agreement signed.
- Control the process by setting dates and limiting visits:
 - Typically one day each at data room and at operation (travel time additional)
 - Additional site visits as necessary
 - Typically one due diligence team per week
- Ensure that data room is well organized with extra copies of important documents available for potential purchasers.

- Record any documents given to potential purchasers for return if they are not the successful bidder.
- Only allow one company at a time in the data room or at the operation.
- Make sure that all units of an operation are up and running.

Buyer's Due Diligence Process—Do's and Don'ts

- Determine what is for sale, what the time constraints are for data room and site visits, when offers need to be submitted, and what constitutes the bidding process.
- Sign a confidentiality/nondisclosure agreement, and obtain an information memorandum.
- Select members of the due diligence team; use consultants when necessary.
- Have a defined scope of work in hand at the start.
- Distribute the information memorandum to the due diligence team; develop a list of questions to ask during management presentations and data room and site visits.
- Never have direct contact with seller if a financial advisor has been retained.
- Request conversations with customers, distributors, and others, if required.
- Consider a preemptive offer.
- Be prepared to make a counteroffer.

TECHNICAL DUE DILIGENCE

Technical due diligence is focused on the reserve, its extraction, and its processing to products.

- Geology and reserves (Santini 1999c)
- Mine plans and operation (Scriven 1999)
- Process plants and facilities (Bentzen 1999)
- Waste management
- Research and development programs

Geology and Reserves

The reserve audit ensures a potential buyer that the reserves, as presented, are a reasonable and accurate approximation of the tonnage or volume and grade/quality of the reserves present (Figure 1). The reserve audit verifies that the reserves may be used for mine planning or economic analysis.

Geology

- Development of a thorough understanding of deposit geology
- Mandatory field inspection
- Examination of drill core/cuttings/bulk samples and review of analytical data
- Review of geologic reports and reserve studies

Reserve Audit

- It is extremely prudent to reestimate a portion of the reserves:
 - Reestimation area(s) must represent deposit and constitute a minimum of 10% to 30% of reserves.
 - Check reserve audit should be at least 90% of the reserve study.
 - If deviations are found in the reserve check, a total reestimation must be done.
 - It is important to determine reserve expansion potential.

- If the reserve audit is within target range ($\geq 90\%$), accept it as being properly compiled.
- If audited reserve is outside target range, indicate where errors exist and the probable impact on overall stated reserve.
- The audit report should provide independent third-party assurance to the buyer.
- Reserves that pass an audit may be used with confidence in preparing cash-flow projections and in deriving net-present value or internal rate of return.
- In performing an audit, there are four general areas of concern that must be checked:
 - Definitions
 - Parameters
 - Data
 - Procedures
- For each of the four general areas, the auditor must be convinced that the reserve study complies with professional standards and industry practices.

MINING DUE DILIGENCE

The due diligence process at a mine or deposit is best done by an engineer with specific knowledge of ore-body/deposit geology (Scriven 1999). For an undeveloped prospect, the investigation may include feasibility of open-pit, underground, or solution mining.

Mine Data

- Feasibility studies, independent engineering reports, and R&D reports
- Mine plans (1-year, 5-year, 10-year, life-of-mine, etc.)
- Movable reserves:
 - Recovery rate
 - Dilution factors
- Geotechnical issues:
 - Rock mechanics (underground)
 - Slope stability (open pit)
 - Subsidence (solution)
- Production schedule:
 - Ore production and grade/quality
 - Waste production and management
 - Stripping ratios
 - Production schedule related to movable reserves (is life of mine accurate?)
- Ore and waste haulage and transport:
 - Capacity of loaders, trucks, belts, hoists, and so forth
 - Haul distance and cycle times
 - Equipment schedule; age and condition of fleet
 - Adequacy to meet production schedules
- Maintenance schedule, procedures, and policies:
 - Written policy
 - History and schedule
 - Equipment needing frequent repairs or total replacement
 - Spare parts inventory, inventory control, storage, and parts flow from suppliers
- Manning schedule:
 - Crew size, shift schedule, tons per man-shift, and unit productivities
 - Age of workforce
- Utility plan (adequate water, power, air, etc.)
- Ventilation plan (new ventilation shafts, fans, etc.)
- Safety and training:
 - Routine training schedule
 - Policy for obtaining and maintaining certifications
 - Policy for attending classes or technical meetings

Mine Costs

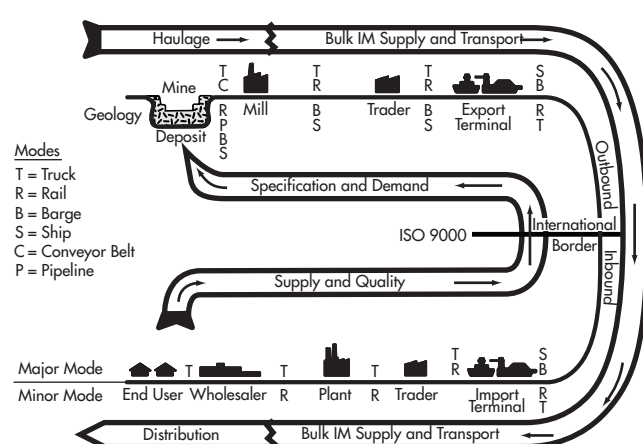

- Fixed and variable operating costs per ton:
 - Labor
 - Equipment
 - Fuel and lubricants
 - Power and water
 - General and administrative
- Capital costs:
 - Replacement
 - Expansion

PROCESSING DUE DILIGENCE

Processing due diligence (Bentzen 1999) involves examining the plant flowsheet, bottlenecks, equipment condition, and replacement costs. This information helps assess how cost competitive the existing plant is compared to similar plants.

Processing Plant

- Flowsheet:
 - Compare original with the actual flowsheet
 - Understand the rationale for recent changes to the flowsheet
 - Describe plant expansion potential and needed changes
- Production capacity:
 - Designed versus actual
 - Availability (percent operating time)
- Production schedule:
 - Production and grade/quality/specifications
 - Waste handling and quantity
 - Matching plant capacity to future production
- Consumption of reagents and other materials
- Review of research proposals and project reports on the process or products
- Manning schedule:
 - Shift size and schedule
 - Age of workforce
- Maintenance schedule, procedures, and policies:
 - Written policy
 - History and schedule
 - Equipment needing frequent repairs or total replacement
 - Spare parts inventory, inventory control, storage, and parts flow from suppliers
- Utility plan:
 - Sources
 - Short- or long-term contracts and renewal costs
- Safety and training:
 - Routine training schedule
 - Policy for obtaining and maintaining certifications
 - Policy for attending classes or technical meetings

Adapted from Barker 1997.

Figure 2. Domestic and export/import transport diagram showing the relationship of the end user to the mine/plant. The various transport modes commonly used at each stage of mineral supply are shown as major (above the line) or minor (below the line). Haulage (off highway) and distribution to end users (delivery) is not usually considered in mineral flow.

Processing Plant Costs

- Fixed and variable operating costs per ton:
 - Labor
 - Equipment
 - Fuel and lubricants
 - Power and water
 - General and administrative
- Capital costs:
 - Replacement
 - Expansion

TRANSPORTATION DUE DILIGENCE

Literature reviews and focus on industrial minerals transport is in Barker and Harben (2004), Barker (1997, 2004), and Barker and Austin (1995). Industrial minerals (IM) transport is complex, often covering multiple modes of transport and frequently crossing international borders (Figure 2). Transport due diligence is not often considered when evaluating other due diligence areas (Barker 1999). An important aspect of due diligence is to see if logistics could be more efficient for incoming raw materials, or outgoing products, or for both. This may be a critical part of the acquisition if increasing transport efficiency helps profitability.

- Cost factors include
 - Type and duration of shipping contracts, if any
 - Mineral or rock produced and form
 - Availability, scheduling, and transit times of desired transport equipment
 - Distance from plant to port, trans-shipper, distributor, or customer
 - Shipment form
 - Handling, docking, warehousing and service companies at each transport change
 - Demurrage exposure

- Insurance and bonding or other risk-avoidance activities
- Government and environmental regulation
- Import and export tariffs and customs
- Cultural or regional differences

• Major transport modes (Table 1):

- Truck (highest cost, most flexible, and most used)
- Rail
- Barge
- Ship (lowest cost, least flexible, least used, but very effective if available)
- Multimodal (use of several modes in one cargo movement)

• Minor transport modes:

- Backpack and pack animal (common in less-developed areas)
- Pipeline
- Postal (small amounts of value-added products)
- Airfreight
- Shipment form:
 - Bulk or packaged (bags, supersacks, cartons, barrels, etc.)
 - Dry or wet (liquid, molten, slurry)
 - Containers

Transportation is more than simply putting products on one mode or another:

- Use of containers and multimodal transport is becoming standard.
- As shipment size or complexity rises, greater care needs to be exercised and use of brokers may be required to lessen risk.
- The buyer must be convinced that the current logistics framework is acceptable or must have a clear idea of the changes needed before acquisition.

MARKETING DUE DILIGENCE

Above all, industrial minerals are market driven, so marketing due diligence is critical (Santini 1999d). Most industrial minerals are sold as raw materials to industry, construction, and agricultural markets. Few (salt, cat litter) are sold directly to consumers. Many individual industrial minerals, through processing differences, yield a variety of products with very different specifications that are sold into very different markets, even when produced from the same deposit with the same mineralogy. For example, glass sand, specialty optical silica, and silica flour for rubber tire manufacture may all come from the same source (Holmes and Santini 1985, 1987 unpublished). Some marketing factors are summarized in Table 2 and in Barker, Austin, and Santini (1999), which includes a detailed outline of an advanced marketing study.

Marketing Categories

- Captive production for use by owner to make a finished product (think internal use)
- Commodity minerals produced in bulk to general specifications (think quantity and low price)
- Specialty minerals produced to meet rigid specifications unique to each customer (think quality)
- Many product lines encompassing both commodity and specialty minerals
- Awareness of where the seller sits in relation to market trends

Table 1. Selected characteristics of transport modes

Characteristics	Truck	Rail	Barge	Ship
Typical U.S. cents/ton-mile	10–25 (high)	2–4 (moderate)	0.75–1 (low)	0.1–0.5 (very low)
Rates and regulation	Negotiated (partly regulated)	Negotiated (partly regulated)	Negotiated (low regulation)	Negotiated (free market)
Flexibility	Very high	Moderate	Low	Very low
Capacity, typical (U.S.)	25 t	100 t	1,200 t	60,000 dwt*
Capacity, typical (Europe)	Varies	Varies	1,500 t	150,000 dwt
Subsidy type	Roadway	Track; land (past)	Locks, waterway	Ports, navigation
Haul containers	Yes	Yes	Yes	Yes
Negotiations (mostly confidential)	Easy; often via regional dispatcher or owner/driver	Hard; railroad often not responsive	Easier with broker, harder without	Less hard with broker, very hard without

Adapted from Barker 1999.

* dwt = dead weight tons.

Table 2. Selected characteristics of marketing commodity versus specialty industrial minerals

Market Characteristics	Commodity Minerals	Specialty Minerals
Place value	High (transport sensitive)	Low (transport insensitive)
Volume	Large	Small
Specifications	Industry standard	End-user customized
Sample evaluation	Short	Long
Properties and uniformity	General	Highly controlled
Testing	Standard	Specific or customized
Substitution	Easy	Hard
Marketing and management style	Business	Technical
Main sales basis	Price (undifferentiated)	Performance (differentiated)
Time to first sale	Short	Medium to long
Rate of market change	Slow to moderate	Rapid to moderate
Need for in-house labs and R&D	Low	High

Adapted from Barker, Austin, and Santini 1999.

Marketing

- Market areas served and market share
- Market studies (company and consultant generated)
- Marketing promotion:
 - Planned and active; results of past efforts
 - Product brochures
 - Trade shows
 - Membership in professional organizations
- Technical sales support:
 - Research and development
 - Technical support offered compared to competitors
- Marketing strengths and weaknesses for each product or line
- Marketing/sales costs

Customers and Distributors

- List of customers
- List of distributors/agents and terms of agreements
- Direct contact with selected customers, distributors, and agents (get approval of seller)
- Volume of sales for company sales staff versus distributors/agents

- Customer service organization and “style”
- Assessment of the company as engineering- or customer-oriented (and whether it should stay that way?)
- Customers satisfaction with products and delivery
- Customers who require ISO (International Organization for Standardization) certification (retain or gain certification?)

Products and Product Lines

- Product types, names, and descriptions
 - Most industrial minerals are marketed by trade name (e.g., Topcoat 90 rather than talc).
 - Consistency and reliable delivery are key success factors.
 - Value-added products have upgraded quality or functionality and thus a higher price.
 - Competitiveness against other producers must be evaluated.
- Quality specifications
- Volume of actual versus budgeted sales
- Annual growth rate (historical/projected)
- Bulk or packaged
- Potential for product substitution

Product Pricing

- Actual versus budgeted
- Pricing structure (contract, spot, list)
- Discounts
- Pricing basis (i.e., f.o.b. or CIF [free on board or cost, insurance, and freight])
- Historical trends
- Forecasts

Sales and Supply Contracts

- Term
- Volume
- Price
- Specifications
- Penalties
- Payment schedule
- Sales revenue

LEGAL AND REGULATORY DUE DILIGENCE

Laws affect every area of an industrial minerals operation, making legal and regulatory due diligence wide ranging (Hayes 1999). These laws affect corporate, tax, environmental, land status, contractual, and a myriad of other functions and factors associated with the asset in question. The various agreements and contractual or regulatory documents uncovered during other portions of the due diligence process will be reviewed by the legal team. Due diligence is seldom purely legal, so consultation is normally done with various appropriate experts.

Legal and Regulatory Due Diligence

- Does the seller own the asset, and have the right to sell it?
- Will the buyer be able to occupy and operate the asset as desired?
- Will the buyer be able to comply with all regulatory constraints to which the asset is subject?
- What current or potential claims exist against the asset?
- Are there guarantees from the seller?

Investigation Effort Required Depends on Nature of Transaction

- Stock acquisition:
 - Buyer acquires the entire entity with all of its assets and liabilities.
 - “Corporate liabilities” include all contract, tort, and statutory claims, even if only remotely related to the desired assets.
 - Such acquisitions typically trigger securities law/regulation issues.
- Asset purchase:
 - It may be possible to separate many of the corporate liabilities from the asset.
 - It is critical to identify those that are attached to asset.

Key Legal Due Diligence Concepts

- Title/limitations on transfer or use:
 - Mining claims, leases, concessions, mining rights, severed rights, water rights, surface access, mill site claims, and so forth.

- Business, personal, and operating property
- Partner/shareholder/foreign entity limitations on change of ownership
- Confidentiality agreements, intellectual property
- Permits, payments, and contracts related to asset operation:
 - Prospecting and mining plans/ permits (including local jurisdiction), permit compliance, and performance bonds
 - Ore/waste haulage contracts
 - Supply/maintenance agreements, equipment leases
 - Royalties; production and property taxes
 - Product sales contracts
 - Distribution/agent agreements
 - Management and union contracts, health and safety plans, retirement obligations
- Corporate affairs:
 - Corporate governance
 - Securities issues (shareholder interactions)
 - Finance
 - Taxes
- Environmental
 - Plans and permits
 - Violations and compliance
 - Bonds
- Litigation
 - Pending lawsuits and threatened actions
 - Judgments, fines, and liens; other regulatory compliance actions
- Seller's representations and warranties

ENVIRONMENTAL SITE ASSESSMENT

An environmental site assessment (Hammond 1999a) is a cost-effective, preliminary, qualitative, environmental investigation conducted to disclose environmental concerns, usually relating to the buyer's risk and liability exposure, prior to the transfer of a property:

- Why: So that environmental hazards or past environmental practices can be identified and disclosed and both the buyer and the seller have a clear understanding of the environmental risks associated with the property transfer
- Where: Any mining or mineral processing property where potential environmental hazards may exist from past or present practices on or adjacent to the site

Reasons for Conducting Environmental Site Assessments in an Acquisition

- To find problems dictating reduction in purchase price or additional indemnification
- To initiate operating practices review
- To identify impediments to permitting/development/production
- To avoid being named the Potentially Responsible Party (PRP)

Phase I Environmental Site Assessments

- Conducted to determine the presence of hazardous or toxic substance contamination at a given site
- Provides sufficient technical information so that a decision regarding the cost/benefit of the transfer can be qualified

- May reveal substances or waste as a result of current or past site activities, unauthorized dumping or disposal, or migration of contaminants from adjacent or nearby properties
- At a minimum include:
 - A review of historical records related to site usage
 - An examination of regulatory agency files and databases
- Includes field reconnaissance of site and adjacent properties
- Characterizes the geological, hydrologic, topographic, and population exposure setting as needed to evaluate potential migration for any contaminants identified
- Normally excludes invasive investigative techniques such as soil sampling, drilling, or groundwater chemical analysis
- Follow formal conduct guidance now provided by ASTM standards E1528-00 and E1527-00

Environmental Site Assessments: The U.S. Regulatory Basis

- Comprehensive Environmental Response Compensation and Liability Act (CERCLA)
- Superfund Amendments and Reauthorization Act (SARA)
- Resource Conservation and Recovery Act (RCRA)
- Clean Air Act
- Clean Air Act Amendments
- Federal Water Pollution Control Act
- Surface Mining Control and Reclamation Act (SMCRA)
- Toxic Substances Control Act
- Occupational Safety and Health Act
- Safe Drinking Water Act
- Hazardous Materials Transportation Act
- Atomic Energy Act
- Endangered Species Act and wildlife regulations

The Phase I Process

- Examination of seller's records and files
- Assembly of maps and geologic/hydrologic information
- State/federal agency interviews and file/database examination
- Air photo examination
- Site inspections and/or overflights
- Operator interviews and document examination
- Interviews with local agencies, residents, and employees
- Documentation
- Conclusions and recommendations
- Business decisions

Contact Agencies in a U.S. Phase I Assessment

- U.S. Environmental Protection Agency
- U.S. Forest Service, U.S. Bureau of Land Management
- U.S. Office of Surface Mining
- State Department of Natural Resources
- State Department of Health
- State Department of Environmental Protection
- Public Utility Commission
- County health department
- Local fire district
- County zoning and planning authorities
- State Conservation Commission

- Department of Public Safety
- State Department of Cultural and Historic Preservation
- Local libraries and historical societies

Regulatory Agency Files and Databases

- Comprehensive Environmental Response, Compensation, and Liability Information System (CERCLIS) registration, assessment, and reports (site location list, event list, National Priorities List [NPL])
- Anthropological, cultural, and historic sites
- Water discharge permits and violations (National Pollutant Discharge Elimination System [NPDES])
- Groundwater and aquifer geology
- Air quality permits and violations
- Solid and hazardous waste disposal (RCRA notifiers, SARA Title III, state permits)
- Mine/operator permits and violations
- Abandoned Mine Land (AML) sites and remediation reports
- Underground storage tank (UST) and leaking underground storage tank (LUST) inventories

Phase I Site Document Review in the United States

- Mine permit or operation plan
- Reclamation plan
- Waste oil management plan
- Regulated waste management plan
- Spill prevention and control plan
- Inert waste disposal permit
- NPDES discharge permit
- Underground injection control permit
- Groundwater discharge permit
- Air emissions permit
- Polychlorinated biphenyls (PCBs) inventory
- RCRA reports
- SARA Title III reports
- Hazardous waste disposal contracts and manifests

Phase I Site Inspections

- Fuel oil storage tanks
- Lubricant/antifreeze storage and distribution
- Maintenance buildings
- Equipment wash facilities
- Hazardous waste collection and storage facilities
- Hazardous materials storage (i.e., solvents, explosives, chemicals, etc.)
- Sewage collection and treatment facilities
- Waste oil collection and storage locations
- Reclamation practices (including what can be disposed of in backfill)
- Underground/surface runoff water control, sediment settling and treatment facilities
- Tailings transport, impoundment, and control
- Laboratories
- Wells and drill holes
- Solid waste disposal sites
- Ore storage sites

- Surplus electrical equipment
- “Bone yards”
- Pits, sinkholes, collapse features, depressions, ground staining, stressed vegetation, refuse piles, discarded containers, barrels, and so on.
- Condition and surface use of surrounding property

FINANCIAL DUE DILIGENCE

Financial due diligence, similar to legal due diligence, affects all areas of an operation and hence requires frequent consultation between team members and other experts. Financial due diligence consists of accounting (Measom 1999), tax (Swearngin 1999), and finance due diligence reviews.

Accounting Due Diligence

- Often overlooked area
- Identification of issues for future financial reporting
- Primary objectives:
 - To verify the completeness, accuracy, and reasonableness of balance sheets
 - To verify that items are not recorded or improperly recorded
- Cash (who keeps it when deal closes)
- Accounts receivable (may need revision language in deal for noncollection)
- Accounts payable (check for unrecorded liabilities)
- Royalties (prepaid or accrued; transferable?)
- Inventories (agree on valuation date)
- Contracts (renewal; transferable?)
- Property plant & equipment (including development and other capitalized costs)
- Mineral reserves (revalue if needed)
- Debt (confirm with creditors; assumable?)
- Equity (stock options, ownership dilution)

Tax Due Diligence

- Tax due diligence involves both the transaction proposed today and projected profit and loss (P&L).
- It focuses on three key areas:
 - Structure of the proposed transaction (taxable or tax free reorganization)
 - Identification and mitigation of hidden tax liabilities
 - Identification and realization of hidden tax benefits

Structure of the Transaction

- Tax-free transactions reduce exposure to hidden tax liabilities and hidden tax benefits:
 - Reduce or eliminate taxes for seller
 - Pass tax attributes to buyer
 - Limitations on future use of tax attributes can be imposed by tax authorities; in the United States, for example, through
 - a. Internal Revenue Code Section 382
 - b. Separate return limitation year (SRLY) provisions
 - c. New regulation creating an “overlap rule” to prevent both Section 382 and SRLY applying to transactions closing after 6/25/99

- Taxable transactions increase exposure to hidden tax liabilities as well as benefits:
 - Consideration should be given to impacts of
 - Income taxes (federal, state, provincial)
 - Sales and use taxes
 - Property taxes
 - Loss of preferred tax status or benefits (i.e., California Proposition 13 grandfather status)
 - Benefits can be associated with step-up in tax basis

Assumption of Hidden Tax Liabilities

- Incomplete tax filings:
 - Verification for all types of taxes related to business activities
 - Verification filings for all jurisdictions in which seller may have conducted business
- Inconsistency in tax filings between buyer and seller:
 - Additional audit exposures
 - Limitation on future filing positions
- Deferred tax liabilities recorded for buyer:
 - Benefits assigned to tax attributes acquired (i.e., net operating loss carry-forwards, capital losses, tax credits)
 - Increase the book value of the acquired assets, therefore impacting future P&L, amortization rates, and so on.

Finance Due Diligence

- Understand current financial structure of the asset (assets, actual and contingent liabilities, shareholder equity, options, etc.).
- Understand deal structure (may trigger audit and other regulatory requirements).
- Identify policies and practices that could have an effect on valuation.
- Perform cash-flow analysis
 - Ability to meet short- and long-term obligations
 - Potential for impairment of assets
 - Reasonableness of pricing and cost structure assumptions

HUMAN RESOURCES DUE DILIGENCE

Human resources (HR) due diligence (Humphries 1999) is a critical area for long-term success of a merger or acquisition. Keeping key personnel on board, on target, and happy greatly eases the almost unavoidable frictions of a successful acquisition.

The Ultimate Scapegoat for a Merger or Acquisition Failure

- Differences in operating style are the most frequently reported post-deal difficulties.
- Cultural incompatibility is blamed for many failures.
- Misconceptions abound:
 - Culture is an intractable force.
 - Culture can be blended gradually.
 - Culture can be changed by preaching.

The Transition Challenge

- Identify the organizational and cultural impediments to an accelerated transition.
- Identify the organizational and cultural constraints on post-transition business performance.

Two Areas of Focus for HR Due Diligence

- Big “HR”—the human resources function:
 - Traditionally, HR is looked at only from standpoint of compliance, risk, and potential negative impact on balance sheet, P&L, or cash flows.
 - It is often an afterthought
- Small “hr”—the human capital of the business:
 - People are generally the “asset” in which significant money is invested.
 - It is essential to look at culture, structure, performance management, and intellectual capital.
 - What is the return on investment (ROI) on people?

Typical HR Due Diligence Areas

- General HR
- General compensation
- Pensions—actuarial
- Compliance
- Postemployment/retirement issues
- Health and welfare
- Executive arrangements
- Organizational and cultural concerns

General HR

- Organizational effectiveness and transition issues
 - HR strategy and structure
 - Efficiency of plan administration
 - Appropriateness of systems; need for new systems
 - Opportunities for outsourcing
- Work force reductions, severance, and payroll tax issues
- Employment compliance, HR policies and procedures
- Labor relations and employee communication
- Cultural factors
- Collective bargaining and unions
- Global work force issues, compensation, and benefits

General Compensation

- Compensation strategy
- Bonus policy and accruals
- Broader stock ownership
- Competitiveness of package

Pensions—Actuarial

- Are all plans identified?
- Are sheltered employees retirement plans (SERPs) active?
- What is plan structure? Whole plan or carve out?
- Are actuarial assumptions okay?
- What are stand-alone expense and buyout/severance impacts?
- Are there unfunded or underfunded international plans?

Compliance

- Are plans compliant with state/national regulations?
- Have filings been made on timely basis?
- Will Pension Benefit Guaranty Corporation (PBGC) be interested?
- Have discrimination tests been satisfied?

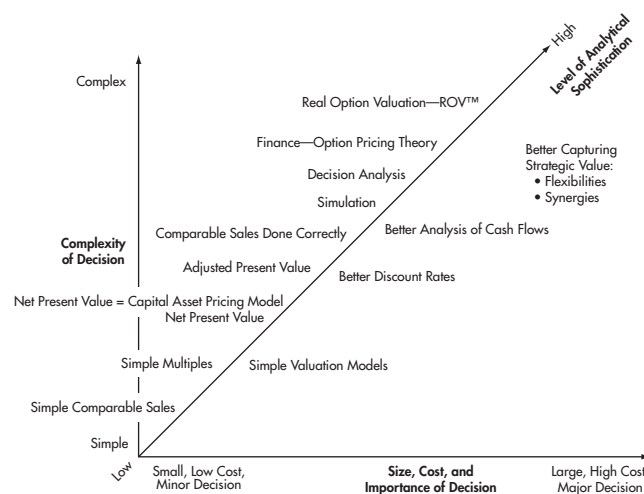

Figure 3. Hierarchy of common methods of asset valuation

- Do stated plan assets actually exist?
- In the United States, are there any Occupational Safety and Health Administration (OSHA) or Equal Employment Opportunity Commission (EEOC) violations?

Postretirement and Postemployment

- If retiree medical/dental and life coverage exist, are there similar issues to pension actuarial?
- Is there reserve for long-term disability (LTD)?
- Is there recurrent severance exposure under FAS 43, particularly for international?
- What is the impact of severance intentions generally?

Health and Welfare

- Current cost of medical and trend—opportunity to reduce cost by managed care or plan design/cost sharing
- Cost of workers' compensation
- Reserve for workers' compensation
- Incurred-but-not-reported (IBNR) reserve for medical and dental
- Cost of insurance coverage

Executive Arrangements

- Employment contracts
- Change in control payments and triggers
- Loss of corporate deductibility and excise tax under Federal Statute 280G
- Accelerated vesting of restricted stock and stock options
- Transition retention and ongoing “incentivization”

VALUATION OF INDUSTRIAL MINERAL ASSETS

No due diligence investigation is complete until the asset has undergone valuation (Hammond 1999b; Hammond and Santini 1999). Figure 3 shows a comparison of some of the common valuation methods.

Valuation Is Part of the Due Diligence Process

- Confirmation of value
- Assessment of risks uncovered during due diligence

- Input for purchase price adjustments (price or deal structure)
- Provision of support for lender appraisals
- Allocation of purchase price for tax and/or accounting purposes

Valuation Defined

- *Webster's*:
 - The act or process of valuing; specifically, an appraisal of property
 - Estimated or determined market value of a thing
 - Judgment or appreciation of worth or character
- Informal:
 - Performed internally or by third party
 - Satisfies business objective
- Formal:
 - Performed by independent third party
 - Often called an “appraisal”
 - Increasingly subject to regulation

Why Do We “Value” Mineral Assets?

- To make decisions (A):
 - Exploration programs
 - Project development
 - Operating strategies
 - Capital budgeting
 - Mergers and acquisitions
- To establish a price (B):
 - Exploration lease/concession bids
 - Asset selling prices
 - Acquisition offers
 - Litigation settlements
 - Financial collateral
 - Purchase price allocation for tax or accounting basis
 - Securities reporting

For A objectives, there may be time to mitigate the impacts of a “bad” valuation; for B objectives, time is often not available.

Standards of Value

- Investment value
- Intrinsic value
- Fair market value
- Fair value

Approaches to Value

- Cost approach
 - Cost to reproduce assets
 - Rarely applicable to mineral reserves
- Market approach (comparable sales)
 - Difficult to identify enough comparable transactions
 - Adjustments usually required to place on truly comparable basis
 - Often best approach for undeveloped resources
- Income approach (cash-flow analysis)

Income-Based Valuation of Industrial Minerals Assets— Developing the Assumptions

Most industrial mineral valuations must be based on a solid market study.

- Market geography:
 - Local
 - Regional
 - Global
 - Current product prices and historical trends
 - Product specifications
 - Impact of competitor capabilities and strategies
 - Potential for product substitution
 - Form in which product is sold
 - Impacts of health, safety, and environmental regulation
- Product pricing projections are usually the most critical model component.
- Different prices for different product forms:
 - Technical specifications
 - Packaging
 - Terms of sale:
 - Existence of a spot or cash market
 - Forward contracts
 - Penalties for out-of-spec material
 - Delivered price and mine netback
 - Transfer pricing when mineral is used as internal feedstock (value-added processing)
 - Export/import tariffs
 - Production capacity sized to the market
- Transportation costs often exceed cost of product:
- Availability
 - Local (e.g., trucking to a railhead)
 - Access to the market (truck, rail, ocean)
 - Transloading and storage
 - Retail distribution
- Marketing costs are often significant for industrial minerals:
- Staff
 - Testing and evaluation (T&E) expense
 - Product quality assurance and control
 - Advertising
 - Inventory

Income-Based Valuation of Industrial Minerals Assets— Building the Model

- Set effective date of the valuation.
- Evaluate lead time for market development that may drive production schedule.
- Escalate/deflate key inputs separately:
 - Product prices
 - Transportation
 - Energy
 - Labor
 - Mine and processing equipment (size to market)

- Include replacement capital.
- Include working capital changes and recovery.
- Include all tax obligations and benefits:
 - Federal, state/province, local
 - Property and use
 - Depreciation, depletion, and amortization shields
 - Tax credits
- Analyze packaging costs:
 - Bags and supersacks
 - Palletizing or containers
 - Quality control
 - Packaging operations
- Assess distribution costs:
 - Warehousing
 - Selling through agents/distributors
- Discount cash flows with appropriate rate for time-value of money.

Income-Based Valuation of Industrial Minerals Assets— Analyzing the Results

- Sensitivity analysis may be useful but often hard to interpret:
 - Production rate
 - Product prices
 - Transportation costs
 - Operating expense
 - Capital expenditures
- As an alternative, build base, upside, and downside cases.
- Probability weight cases to generate expected value.
- Test using comparable sales if data is available.
- “Residual values” can be very important, especially when a low discount rate is assumed.
- Depletion allowances for industrial minerals vary widely for federal taxes in the United States:
 - 5% (sand and gravel) to 22% (fluorspar)
 - Sometimes depends on product form
- Incorporation of financing provisions should reflect “purpose” of the valuation.
- Choose corporate or “stand-alone” analysis.
- Make adjustments to the spreadsheet discounting formula:
 - Mid- or end-of-period
 - Continuous versus discrete

SUSTAINABLE DEVELOPMENT

Sustainable development (SD) is a complex, poorly understood group of social concepts gaining worldwide acceptance as a new way to organize interactions with society. It is discussed in more detail in another chapter in this book. Benefits to mining include gaining and maintaining the critical social license to operate. SD is much more than performing legally required reclamation and calling it sufficient. True SD involves engaging all stakeholders in a given mining venture early, often, and continuously through the entire life of the project with the goal of leaving them with positive benefits after the postclosure activities have been completed. Mining SD is discussed in IIED and WBCSD (2002), Barker (2004), Langer (2005), and Barker and McLemore (2005), among many others. As

Markley (2005) stated relative to the aggregate industry “[SD] activities will move beyond something necessary for success to something necessary for survival.”

A convenient way to quickly evaluate SD is to get answers to the seven questions (IIED and WBCSD 2002; *E&MJ* 2005) commonly used to evaluate an SD program:

- Are engagement processes in place and working effectively?
- Will people’s well-being be maintained or improved during and after the project or operation?
- Will the integrity of the environment be taken care of in the long term?
- Is the economic viability of the company ensured; is the community and regional economy better off not only during operation but into postclosure?
- Is the viability of traditional and nonmarketing activities in the community and surrounding area maintained or improved with the project or operation?
- Are the rules, incentives, and capacities currently in place and will they remain as long as required to address project or operational consequences?
- Does the evaluation show the project to be net positive or negative for people and ecosystems; is a system in place to repeat the assessment from time to time?

SUMMARY

A thorough due diligence investigation before purchasing an asset is necessary to identify both risks and rewards and to determine value. Due diligence applies to both the buyer and seller and has legal ramifications. “Buyer beware” is somewhat tempered by the requirement of the seller to be forthcoming. The buyer has an obligation to understand the asset, so due diligence is required. In addition, for a successful transaction to take place, the buyer must be willing to pay a price for the asset that is acceptable to the seller, under terms and conditions acceptable to both parties.

Rail Transportation of Industrial Minerals

Charles N. Speltz

BACKGROUND

The history of railroading began in England, in 1797, with the invention of the steam locomotive. U. S. railroading followed shortly thereafter, in 1827, when the first railroad was constructed in the United States—the Baltimore and Ohio. In 1869 the United States was connected coast-to-coast by the first transcontinental railroad. Others followed until, in the zenith of U.S. railroading in 1916—the United States could boast of 254,000 miles of rail (Association of American Railroads 2004b).

By 1980, however, U.S. railroads were in trouble. Excessive regulation by the Interstate Commerce Commission (ICC), coupled with onerous work rules promulgated during the period of regulation, had driven the railroad industry to the brink of insolvency. Twenty-one percent of the nation's track mileage was operating under the protection of bankruptcy courts. Infrastructure maintenance and improvement had been deferred or ignored. The railroad's rate of return on investment was less than 3% (Ekelund and Hebert 1988).

Furthermore, the response of the railroad industry to business sectors that did not generate adequate rates of return was to decrease service, or raise prices, until they became unprofitable or were overtaken by another industry. Witness the loss of passenger service to the airlines, the loss of small-package delivery to intercity buses and parcel delivery services, and the loss of less-than-carload shipments to interstate truckers.

In 1980, the U.S. government passed the Staggers Rail Act. This act eliminated most of the regulatory authority held by the ICC. The act recognized that the railroads no longer had a monopoly on surface transportation and that truck and river transport could and did compete with rail. It also recognized that two-thirds of intercity freight was being moved by non-rail carriers and that if the railroads were unable to increase their rate of return on investment, then the rail system of the country would continue to deteriorate (Ekelund and Hebert 1988).

Although Staggers did not totally deregulate U.S. railroads, the act gave the railroads the opportunity to eliminate inefficient revenue-producing track; enabled the railroads to more easily merge; and most importantly, freed the railroads to confidentially contract freight rates without governmental review or approval. Deregulation has improved the rate of return for railroads, has financed deferred maintenance, and in general terms, has allowed the railroads of the United States to return to health.

Problems still exist, but they are now largely caused by the monopolistic structure of the nation's rail network, which has concentrated itself through merger from 40 Class I railroads in 1980 into 6 Class I railroads today. Some believe that this concentration has resulted in monopolistic behavior by the railroads resulting in problems for customers as well as operating inefficiencies for the rail system itself.

Most complaints involve poor service, high costs for services rendered, or both, and these directly affect the industrial minerals industry. Incorrectly routed, lost, or delayed railcars seem to be the most prevalent complaint; however, the seemingly complete inability to reliably deliver railcars on schedule is a close second.

Most significant is the so-called practice of "differential pricing" wherein the railroads are perceived to "price gouge" customers served by a single railroad to make up revenue that is lost to customers served by more than one railroad (Baker 2003).

Many critics of the existing rail system feel that the best solution for the nation's railroads is to create unbridled competition by permitting "open access" or "competitive access," wherein any customer served by a single carrier could receive competitive rail service by other rail carriers. Needless to say, U.S. railroad operators deny that they price gouge some customers in favor of others and argue that any system of open or competitive access would be confiscatory and not serve the public good.

Regardless of the problems facing the rail industry today, when shippers have many transportation options, the railroad is, far and above, the most significant and economically viable transportation means for the U.S. minerals industry.

In 2003, U.S. railroads transported 958 billion metric tons (1,055 billion short tons) of mineral commodities including coal, metallic minerals, finished products, industrial minerals, and sand and gravel. In the same year, the minerals industry earned U.S. railroads revenues of \$11.8 billion, approximately 31% of the total revenues earned by the entire U.S. rail industry.

In 2004, U.S. railroads delivered 1,509 billion metric-ton miles (1,663 billion short-ton miles) of freight service at an average cost of 2.59¢ per metric-ton mile (2.354¢ per short-ton mile) (Association of American Railroads 2004a).

This average cost of 2.354¢ per short-ton mile demonstrates the importance of rail transportation to the minerals industries. Relative to other commodities, many minerals or mineral products (especially industrial minerals) are low-value commodities. Freight

charges are often several times greater than the cost of the mineral. Because of this generally low value of industrial minerals, low-cost, economical surface transportation is critical to the well-being of the minerals industry and the nation.

THE RAILROAD AS TRANSPORTATION

Rail transportation is one of four domestic methods for long-distance surface transportation of mineral commodities, the others being over-the-road trucks and navigable river and coastal shipping.

Rail movement of goods, like water transportation, is an inflexible method of transportation. Water transportation can serve only those locations with access to navigable water. Rail delivery can only serve those locations that have rail access. Regardless of economics, or desirability of rail service, if a location is not served by a rail system, it cannot avail itself of the generally lower prices provided by rail transport. Construction of new rail service is frequently not practical because it is expensive and must be paid for by the customer. The rail companies no longer pay for new rail construction.

The inflexibility of the rail system affects the shipper in two ways. First, a truck can generally load and discharge at any source or destination—rail cannot. Second, truck shipments can be scheduled; train delivery dates can only be approximated.

Further, rail service is not time sensitive. An average train consists of 48 cars, most carrying differing commodities, shipped from different origins, and consigned to different destinations. This heterogeneity demands that the train be assembled at some central point of origin, perhaps disassembled, sometimes more than once, at some intermediate station, and finally classified for local delivery to the final destination. A truck can be driven directly from one point to another and a very precise schedule can be maintained. The additional handling required by rail shipments creates a situation in which schedules are approximate at best and completely fallacious at worst.

RAILROADS IN THE UNITED STATES

Three classes of common carrier and one class of noncommon carrier railroads operate in the United States as defined by the Surface Transportation Board (STB); the three classes are defined by annual gross revenues for purposes of accounting and reporting (Bureau of Transportation Statistics 2004):

- Class I. Rail companies with annual operating revenues of \$277.7 million or more are usually termed “mainline” railroads.
- Class II. Rail companies with annual operating revenues of more than \$40 million but less than \$277.7 million are usually referred to as “regional” railroads.
- Class III. Rail companies with annual operating revenues of less than \$40 million are generally called “short-line,” “local line-haul,” or “terminal” railroads.
- Private. Rail companies that are privately owned and not common carriers are private railroads.

Class I—Mainline Railroads

There are six Class I (mainline) railroads operating in the United States (Baker 2003):

1. Burlington Northern Santa Fe (BNSF)
2. Norfolk Southern (NS)
3. Union Pacific (UPRR)
4. Canadian National (CN)/Illinois Central (IC)
5. CSX Transportation (CSXT)
6. Kansas City Southern (KCS)

Additionally, the Canadian Pacific Railroad, which owns the Soo Line and two Mexican railroads, Ferrocarril Mexicano and Transportacion Ferroviaria Mexicana, would be considered Class I railroads if they operated in the United States.

Class I railroads are common carriers. They are interstate railroads, with BNSF and UPRR dominating the region of the United States west of the Mississippi River; the NS and CSXT monopolizing the region east of the Mississippi; and KCS and CN Railways being principal players in the vital north-south corridor, more or less paralleling the Mississippi River.

Each of the Class I railroads is a monopoly. Each owns its rights-of-way and its tracks and equipment, and each maintains the exclusive right to operate over its system. Each railroad has complete freedom to raise or lower freight rates, accept or refuse new business, and deny customers competitive rail service from other carriers. Only when it is not advantageous to exercise their monopolistic power, specifically in the area of “reciprocal switching,” will railroads choose not to exercise their monopolies.

Monopolistic power was diluted by the STB as a condition of merger under the terms of the Staggers Act. If a customer was served by more than one rail carrier before a merger and the result of the merger would deny that customer access to multiple carriers, mergers were structured by the federal government so that those customers having prior service from multiple rail carriers would still have that multiple service after the merger. “Switching rights” were extended to competing rail carriers so that those customers deprived of multiple rail carrier service as a result of the merger would regain that multiple service.

Furthermore, many mainline systems granted to other competing carriers, as additional conditions of merger, operating rights over parts of their systems. Such grants are termed “trackage rights” and give the competing carrier the right to use tracks it does not own for a fee. Such rights usually prohibit the owner of those rights from serving any existing customers that did not have multiple rail system service before the merger.

For example, in 1995, when the Union Pacific merged with the Southern Pacific, the BNSF was granted trackage rights from Denver to the San Francisco Bay area and specifically, in conjunction with the Utah Railroad, was granted rights to the eastern Utah coal fields and other Utah industries that previously enjoyed multiple rail carrier service.

Mainline systems generally cooperate well with one another when cooperation suits their purposes, but the shipper cannot expect that cooperation to be extended to their private requirements.

In general terms, mainline systems will compete with one another when competition is direct, but no system, mainline or regional, will reduce its rates unless it finds that rate reduction in its own best interests.

Developing a totally new mine or processing facility is the only way to gain service using trackage rights held by an alternate carrier who does not own the track. The new mine or processing facility must install new rail access. Use of previously existing rail access is sufficient reason for the track's owner to deny use of the alternative carrier's trackage rights. Alternatively, trackage rights can be used by an existing facility if that existing facility did not previously use rail transportation and if new rail access is constructed.

Managerial Tip 1

Railroad marketing does not accept hypothetical or possible competition as reality. A threat, written or verbal, to change transportation schemes is ineffective. Competitive pricing is spurred only by the actual commencement of shipping by an alternative method, by truck or rail, or through the construction and use of a trans-loading terminal.

Managerial Tip 2

The most economical scheme of rail shipping is via a single line. Single-line shipments are referred to as a “single-line haul” or “direct haul.” On occasion, single-line hauls are termed “local,” even when the delivery is interstate. When a direct haul is not possible, railroads will attempt to maximize the distance a shipment moves on its lines, even if an alternative route is more advantageous to the shipper.

Rail movements using two separate carriers, end to end, will cost the same as if the movement were made on two separate, unrelated, unconnected, and independent systems. Exceptions exist; if one of the rail systems is attempting to increase traffic on the rail segment to be used, better pricing may be available. Alternatively, if competition exists, perhaps an alternate route using another carrier, most carriers will accept some level of revenue over nothing, assuming that the carrier has any desire for the business.

Class II—Regional Railroads

Regional railroads, which can best be described as small mainline railroads, are common carriers. They are indistinguishable from Class I railroads except for geographic extent and total gross revenue. Regional railroads serve smaller geographical areas but are subject to the same operating rules as Class I railroads.

Class III—Short-Line Railroads (Local Line-Haul, Switching, and Terminal Railroads)

Short-line railroads, including local line-haul and terminal railroads, are those small rail systems that cannot be economically operated by the mainline or regional carriers. They frequently consist of sections of mainline railroad that would have been abandoned by the Class I or II railroads if not acquired by an independent operator.

Most short-line railroads were created because the rail segment had too few customers or low traffic volume and was unable to generate sufficient revenue to justify continued operation under the ownership and work rules of a mainline or regional carrier.

Switching railroads are created to provide switching services to a specific area in which the Class I railroad is unable to offer cost-effective service. If a switching railroad services a port, it can be termed a terminal railroad. The terms switching and terminal railroads are frequently interchanged.

As an example, Rail Link, Inc., operates a switching, or terminal, railroad at the Port of Greater Baton Rouge in Louisiana. Originally the port was switched by the Union Pacific, but the Union Pacific was unable to economically provide the level of service demanded by the port authority (the Greater Baton Rouge Port Commission).

Other short-line railroads were created when mergers between two mainline or regional railroads provided parallel service to common destinations. One of the two parallel routes became redundant and was slated for sale or abandonment.

As an example, the Atchison, Topeka and Santa Fe Railroad had tracks from Fort Worth, Texas, to Brownwood and Temple, Texas, with a line between the latter two towns. The westernmost route, from Fort Worth to Brownwood, was deemed surplus and was sold to the South Orient Railroad.

Most short-line railroads are captive to the Class I railroad that permitted their creation. This captivity to the Class I, which created the short line, is termed a “paper barrier.” A captive short line is “closed” to interchange with other carriers. For example, the San Luis and Rio Grande Railroad operating from Walsenberg to Antonito, Colorado, is a short line created from Union Pacific assets. Although the San Luis and Rio Grande terminates at Walsenberg, an interchange point with the BNSF, it is captive to and interchanges only with the Union Pacific. It is closed to the BNSF.

Exceptions do exist. If the rail line converting to a short line interchanged with multiple carriers before becoming a short line, it will continue to interchange with multiple mainline systems. For example, the Montana Rail Link, originally belonging to the Burlington Northern system, operates from Billings, Montana, to Spokane, Washington, and interchanges with the BNSF at four separate points; with the Montana Western at Garrison, Montana; and with the Union Pacific at Sandpoint, Idaho.

Short lines are smaller, less bureaucratic, have fewer work-rule provisions, and are often more flexible than mainline systems. In most cases, a short-line railroad is capable of offering more personalized problem-solving service than the larger railroads.

Private Railroads

Private railroads are not common carriers, are generally dedicated to serving a single customer, and have been purchased or constructed specifically to serve that customer.

A mainline system may want to abandon a short, underperforming, inadequate-revenue-producing branch line, perhaps a line serving a single customer. But the line is too short or economically incapable of supporting a short-line railroad. Any customer situated on such a branch line may be forced to acquire the track or be denied future rail service.

Alternatively, a customer captive to a single carrier may find it advantageous to construct a private railroad to connect with a second carrier. Construction of the branch line creates instant competition and should serve to reduce freight rates.

PRACTICAL CONSIDERATIONS OF THE FOUR CLASSES OF RAILROADS

Mine operators cannot choose their rail service providers because mines are located where the mineral to be mined is found. Most mines are remote and are indeed fortunate to have any rail service at all.

If a mill or processing plant is planned and precise location is not an issue, that facility should be constructed with direct access to two rail systems. As an alternative, the facility should be sited on a short-line railroad that provides access to multiple carriers. Competition between two carriers will keep transportation costs lower than if the facility is captive to any single carrier.

Competing railroads work well together when given no other choice. The originating railroad defines the route, and will attempt to maximize the distance that a shipment travels on its system and minimize the distance traveled on a competitive system. If the destination is open to reciprocal switching, the shipper will likely suffer no harm. If the destination is not open to reciprocal switching, however, the receiving carrier will define its portion as a line haul

and likely charge a disproportionately higher tariff for completing the shipment.

In such a case, the shipper may be able to negotiate some other intermediate interchange point so that both carriers will receive a more proportionate share of the transportation charge. The originating carrier has little or no incentive to shorten its share of the route because its division of the total revenue is proportional to its share of the route. When confronted with the choice to cooperate with another rail carrier or lose the business, railroads are likely to decide that a little less revenue is better than no revenue at all.

RAILROADS AND THE INTERNET

The Internet has radically changed the relationship between railroads and their customers. Before the Internet, all business between the railroads and their customers was conducted by telephone, fax, or surface mail. Surface mail was slow, faxed instructions proved to be unsatisfactory, and telephone instructions were often misinterpreted. The computer, modem, and Internet changed everything, making instantaneous communication possible and creating a permanent record of instructions sent and received. No longer can a verbal miscommunication serve as an excuse for mistaken instructions.

All six Class I rail systems, as well as the two Canadian systems, Canadian Pacific and the Canadian National, have Web sites. The two Mexican railroads do not. All Class I and II railroads are rapidly converting exclusively to Internet instructions and orders. A customer using verbal or written orders or instructions, for whatever reason, can expect to pay a fee for such usage.

Web sites of the various railroads and their capabilities are given in the Establish Business Relationship section of this chapter.

RAILROAD EQUIPMENT (ROLLING STOCK)

Railroad equipment or “rolling stock” exists to provide virtually any service that the mineral industry requires. Operators use open-top cars when the cargo is not weather-sensitive, covered cars for weather-sensitive materials, tank cars for liquids, low-volume cars for dense materials, high-volume cars for low-density products, and specialized cars for unusual situations.

Crude mineral transportation is most commonly accomplished with open-top cars, either gondolas or hoppers. Gondolas are either “low” or “high” sided. Hoppers are open for transport of crude, non-weather-sensitive products or covered for transport of processed, dry, or finely divided mineral products.

Gondolas

All gondolas are open-topped and subject to weather, wind erosion, and contamination from thrown objects. There are no restrictions to cargo type, except that the shipment of hazardous wastes or materials requires special permission.

Low-side gondolas are referred to as “scrap cars” because one of their primary uses is to transport scrap metal. Low-sides are available in two lengths, 52 ft and 65 ft, and have an overall height of less than 9 ft. Low-sides are often delivered contaminated or dirty from previous service. Although railroad regulations require that cars be returned sufficiently clean to reload with another commodity, reality dictates—particularly when the car has been in scrap service—that corners, dimples, and structural irregularities sometimes trap contaminants.

Low-side gondolas are most frequently used to ship oversize materials, such as riprap or dimension stone, and difficult-to-unload materials such as bauxite, clay, iron ore fines, and nonferrous metal concentrates.

Low-side gondolas are frequently in poor structural condition with moderate to severe damage to the sides and bottom of the

Courtesy of Charles Speltz.

Figure 1. Low-side gondolas loaded with bauxite

cargo box from loading and unloading of scrap metals, steel, pipe, and other heavy materials. The side walls of the car are often bent outward, a condition referred to as “bowed out.” Although not specifically harmful to the commodity being loaded, a bowed-out car provides an opportunity to load cargo off-center. Off-center loading is discussed in the Receive and Load Cars section in this chapter.

Low-side gondolas must be loaded and unloaded from the top. Common machinery for unloading gondolas are crane-mounted clamshell buckets, hydraulic excavators operating from the side or above the car, and specially equipped backhoe tractors or excavators mounted on top of the car (Figure 1).

Hydraulic excavators can operate from the top of the cargo if the cars are loaded to full, visible capacity. If not loaded in this way, the excavator must operate from movable decks set on top of the car. Either technique is a low-to-medium-unloading system capable of unloading 10 to 20 cars in a single 8-hr shift.

Specially equipped backhoe tractors, riding along the side rails of gondolas, furnish a very safe, economical method of unloading gondolas. Because of the maximum size of the bucket on backhoes, however, daily output is less than that achieved by hydraulic excavators.

Because of their inability to reclaim material from the ends and corners of the cars, clamshell buckets or hydraulic excavators working over the side of the car require additional labor, or a small skid-steer loader, to thoroughly clean the cars. Neither technique is a high-volume unloading method and neither is recommended for sustained operations.

High-side gondolas, sometimes referred to as “bathtubs,” are 11 ft tall or higher and are normally used to transport lower density materials such as coal or coke (Figure 2).

High-side gondolas are frequently unloaded by rotary dump wherein the entire car is turned upside down and the cargo is discharged through the top of the car. Top-mounted backhoes or hydraulic excavators operating from the top of the car are also used.

Hydraulic excavators operating from alongside the car are not acceptable for unloading high-side gondolas because the boom of the excavator cannot reach the bottom of the car.

Open-Top Hoppers

Open-top hoppers are the most common railcar used to transport crude mineral commodities (Figure 3). Frequently referred to as “coal cars,” open-top hoppers are mainly used to ship coal, sand and gravel, and crude minerals and ores. Open-tops have a volume between 3,610 and 4,000 cu ft and carry between 93 and 115 net

Figure 3. Open-top, cross-dump hopper

short tons. Open-tops, like gondolas, are subject to weather, contamination from thrown objects, and wind erosion of contained cargo.

Open-top hoppers are not acceptable for oversize products such as riprap, mine-run, uncrushed rock or ore; non-free-flowing materials such as bauxite; or wet, mineral concentrates.

Open-top hoppers are equipped with doors on the bottom of the car. Hoppers with doors mounted perpendicular to the axis of the car are termed "cross-dump hoppers," and those with doors parallel to the axis of the car are called "side-dump hoppers." Side-dump hoppers are primarily used for ballast distribution and are not usually available for commercial applications.

Some open-top hoppers are equipped with rotary couplers that allow the car to be completely overturned and emptied without uncoupling the cars. Rotary dump cars are usually identified by a solid color band on each end of the car (Figure 4).

Open-top hoppers are constructed with 33- or 45-degree end plates. The shallower end plates are applicable to the shipment of gravel; clean, crushed stone; and other free-flowing materials. The steeper end plates should be used for coal, coke, sand, soil, and other non-free-flowing materials. Railroad managers have created mainline systems with a mixture of open-top hoppers. Carriers are unwilling to guarantee delivery of cars with a specified end-plate slope; the customer must use what is delivered.

Courtesy of Charles Speltz.

Figure 4. Bottom-dump hopper with rotary couplers (note that one end of the car is painted white, signifying that the car is equipped with rotary couplers)

Open-top hoppers require supervision when unloading is complete. Railroad regulations require that all doors be closed and locked before release of empties. Although hopper doors are often difficult to close and lock, level of difficulty is no excuse for leaving doors open or unlocked. Open doors can swing violently, snag the rail, or break loose from the car. They are a recognized safety hazard and have even caused derailments.

Switching crews have instructions not to move cars with open doors. Demurrage (see Accessorial Charges section) incurred as a result of open doors is difficult to protest. Further, rail tariffs allow for extra charges if the railroad must close doors.

When confronted by doors that cannot be closed and locked, the car should be reported as "bad order" because of defective doors. The railroad is then responsible and has no recourse to the customer.

Managerial Tip 3

Covered Hoppers

Covered hoppers are completely enclosed, sealed, weatherproof, windproof, and secure from thrown objects (Figure 5). Covered hoppers are loaded from the top through longitudinal or circular doors aligned on both sides of the top of the car. Cargo is discharged from sliding gate doors arrayed along the bottom of the car.

Covered hoppers range in volume from 2,000 to 5,000 cu ft and have capacities up to 110 net tons. They are most applicable for transportation of dry, fine mineral such as cement, lime, bentonite, phosphate, perlite, or soda ash.

Pressure Differential (Discharge) Cars

On first glance, pressure differential cars (pneumatic or "PD" cars) look like covered hoppers except for the plumbing found on the bottom of the cars (Figure 6). In effect, PD cars are large "pressure pots" from which the contents of the car are removed pneumatically. Low-pressure air, usually between 7 and 10 psi, forces the contents of the car downward through a metering device, either a

Courtesy of Charles Speltz.

Figure 5. Covered hopper

gate or a rotary valve, into a high-volume stream of low-pressure air that delivers the product to storage, either truck or silo.

Low-pressure air is provided either from a stationary source, usually a high-horsepower root blower, or from the delivering truck using a transmission-mounted “power-take-off.” In most cases, because of its higher power and higher air volumes, a stationary source of air delivers faster, more economical delivery of product.

PD cars are most often used for delivery of portland cement, fly ash, hydrated lime, and any other dry, finely divided products. Although materials as coarse as $\frac{3}{4}$ in. may be unloaded pneumatically, the efficiency of the operation is indirectly proportional to the size of the product. A given stream of low-pressure air will move more finely divided than coarse material.

Pneumatic transportation should not be used when product degradation is an issue. For example, oil-well proppant (frac) sand, even though delivered and used pneumatically at the job site, should not be transported in PD cars because the unloading process will degrade particle size and generate undesirable fines.

Rail companies rarely, if ever, have pneumatic cars available as part of their car fleet. In most cases, PD cars are owned or leased by the shipper and they are almost always dedicated to shipping a single product. Exceptions to this rule exist when the empty railcar can be completely cleaned (usually water washed), before reloading with a different product or where the products are mutually compatible, such as portland cement and fly ash.

Tank Cars

Tank cars are tanks on railway wheels and are used to transport liquids (Figure 7). Most commonly used to carry oil, asphalt, liquid chemicals, and other petroleum products, tank cars are also used by the industrial minerals industry to transport brines.

Specialized Cars

Bottom-Dump Gondolas

This type of gondola (Type E-equipped gondola) is rare, almost extinct. If any still exist, they are almost certainly in private fleets.

Drop-End Gondolas

These are available in both low- and high-sided configurations, and are equipped with a lockable door on each end of the car. Drop-ends allow a small tractor to enter the car from the end and unload cargo.

Like open-top hoppers, all doors on covered-top hoppers must be closed and locked prior to shipment. Unlike open-top hoppers, covered hoppers have doors on both the top and bottom; both sets must be closed and locked. Open doors on the top have blown off. Because of their cantilevered construction, open doors on the bottom have become warped, bent, and unclosable. Warped bottom doors permit leakage and loss of product. Shippers are responsible for accepting cars tendered by a railroad for loading. When a car is loaded and billed, the shipper acknowledges that the car was suitable for use, and any leakage or loss of product is the shipper's responsibility.

Figure 7. Tank car

Courtesy of Charles Speltz.

Figure 8. Side-dump gondola

Drop-end gondolas are most commonly used to carry wood products such as wood chips or sawdust, but they are also used to transport mineral products.

Side-Dump Gondolas

Sometimes referred to as “riprap cars,” these gondolas are used to carry and discharge oversized materials, most commonly mine-run ore or riprap (Figure 8). Side-dumps are equipped with pneumatic cylinders that rotate the entire car body while simultaneously lowering the side walls. Cars can only be discharged where high-pressure (100–125 psi) compressed air is available, either from a locomotive or from an external supply.

Side-dumps allow cargo to be discharged alongside the track at any location served by rail. They are most frequently used to deliver riprap or ballast to the point of use without unloading and transshipment from an intermediate location.

Railroad companies have a limited supply of side-dump gondolas and are reluctant to allow their use for any nonrailroad application. Most side-dumps are privately owned, available from rail-served open-pit mines, and generally in poor physical condition. In addition, side-dumps are heavy with substantially higher tare weights than either gondolas or hopper cars.

Iron Ore Cars

Iron ore cars (“taconite” or “T1” cars) are manufactured to handle dense materials such as iron ore, taconite pellets, or metal concentrates. They are short, usually about 33 ft long (versus 55 ft for a standard hopper or gondola), are more heavily constructed than other cars, and are equipped with heavy-duty doors to withstand dense materials.

Taconite cars are generally not available for commercial use outside the iron ore industry.

Molten Sulfur Cars

Molten sulfur cars are used to transport sulfur in a molten state. The cars are equipped with internal steam pipes to re-melt the contents of the car. The melting temperature of sulfur is 245°F, and it will remain molten for a considerable period after loading. The exact duration depends on outside temperatures.

THE RAIL SHIPPING PROCESS

The shipping process consists of 11 steps:

1. Establish business relationship.
2. Determine car type.

3. Determine freight rates.
4. Order cars.
5. Receive and load cars.
6. Release loads and bill.
7. Monitor and trace cars.
8. Receive loads.
9. Unload cars.
10. Release empty cars.
11. Pay freight bill.

Establish Business Relationship

The initial step in dealing with any railroad is to establish a business relationship that includes credit arrangements. The initial portal into a railroad system is via the customer service department or the World Wide Web site for each railroad.

Although the customer service departments will not actually provide such entry, they will refer the new shipper to the appropriate departments to discuss shipping needs, arrange credit, provide instructions for entry into the appropriate electronic commerce programs, and generally facilitate the creation of the business relationship.

The customer service phone number and Web home page for each mainline railroad follow

UPRR	(800) 272-8777, www.up.com
BNSF	(888) 428-2673, www.bnsf.com
CN/IC	(800) 601-7630, www.cn.ca
NS	(800) 635-5768, www.nscorp.com
CSXT	(577) 744-7279, www.csx.com
KCS	(800) 282-8700, www.kcsi.com

A knowledgeable sales representative will be assigned depending on the size of the customer and the railroad system to be used. The representative will assist the customer in all steps involved in building a business relationship with the railroad.

Determine Car Type

The type of railcar to be used is based on the product to be shipped and the method of loading and unloading. Once the car type and capacity is selected, determine if the originating railroad can supply the cars. If another railroad is involved, can the other railroad furnish the cars? Are private cars available? Should they be purchased or leased? What is their monthly cost? What are the lease terms?

Railroad companies will not construct or pay for new access to projects. In the past, the customer desiring new access paid for the construction of that access, and the rail carrier offered an allowance based on traffic actually shipped to pay for the construction. Such an allowance no longer exists. There is no reference to such an allowance in any railroad publication.

Such an allowance is available, however, as part and parcel of any negotiations involved in negotiating rail service for a new project. Any allowance would be given as a freight rate reduction, not as a construction allowance.

Sales personnel for the railroads will not voluntarily offer such an allowance, but if the railroad wants the business, particularly if there is competition with another carrier, such an allowance is available and negotiable.

Managerial Tip 5

Table 1. Types of freight pricing documents

Class of Document	Type of Document	Characteristics of Document
Public	Public tariffs	Available on Internet
	Open quotes	Group rates
	Price lists	Point-to-point
		Mileage rates
Private	Contracts	Confidential
	Letter quotes	Single-party
		Single-commodity
		One origin
		One destination

Does the railroad provide any price relief if private cars are used? A full-service lease (triple net) includes lease cost, car maintenance, property insurance, and taxes; leases are available in any combination. Does the movement or contract justify purchase or lease?

Determine Freight Rates

There are two types of pricing agreements for determining freight rates: public and private (Table 1).

Public pricing documents—whether published as tariffs, price lists, or open quotes—are available to any rail shipper. They are not confidential, are open to the public, and are available either in hard copy (although hard copies are being phased out) or via the Internet. Today, shippers requiring hard copies can print them directly from the Web pages of the publishing railroad. Public rates are most applicable to the occasional or low-volume shipper. Whenever a public price is used to make a shipment, reference to the source document should be made on shipping documents.

U.S. railroads quote prices by commodity in three formats. They are

1. Point-to-point is the most specific format and is preferred over other formats. The origin and destination are specified.
2. Group-to-group rates define origins and destinations as geographic groups. If available, point-to-point rates supersede group-to-group rates.
3. Mileage rates are determined by distance, which is found in a railroad publication or on the Internet. Both point-to-point and group-to-group supersede mileage rates.

All railroad price quotations are commodity specific. Transporting higher-value commodities costs more than transporting lower-value commodities.

Shipments must be properly identified for purposes of determining freight rates. If a carrier determines that a commodity is being shipped under an improper tariff (i.e., it is being shipped as a lower-value commodity to gain a lower transportation charge), the carrier may adjust the freight bill to reflect the proper commodity and tariff charge. Also, if a shipment is lost or damaged and was tendered on an improper rate, the railroad may refuse to honor any claim to recover the loss because the shipment was improperly tendered. In any case, the claim would be settled for the value of the lower-priced commodity, not the actual value of the improperly tendered commodity.

Public freight rates can be found on the Internet or in the specific pricing publications of the rail service provider.

If a specific rate cannot be found, requests for freight rates can be made to the customer service departments of each railroad. In most cases, requests must be made via the Internet or via e-mail to the appropriate customer representative. At a minimum, a request

Determination of a proper STCC is subjective. In many cases, a given commodity may fit into more than one STCC group. There is no prohibition against shipping on the most advantageous STCC number as long as that STCC number fairly identifies the commodity being shipped and is not simply a subterfuge for obtaining a lower transportation rate.

Managerial Tip 6

must include the name of the shipper and receiver, the location of each, the commodity and its Standard Transportation Commodity Code (STCC), the size of shipments to be made, the anticipated annual volume, the type and owner of the cars, the name of a contact person, and the phone number and e-mail address of the contact person. The customer service representative will request any other requirements.

STCCs are available through most of the Web pages of the Class I railroads. If the railroad provides computerized freight rates, there is a way to look up the commodity code.

If a public rate quote precludes a shipment, perhaps the price quoted is too high; private quotes might be available if the shipment is sufficiently large or long term. Private quotes are negotiated with the appropriate customer service representative or commodity specialist for the specific commodity being shipped. Private rate quotes are not available for single-car or intermittent shipments.

Letter quotes are short-form contractual freight quotes. Like full contracts, they are confidential and usually apply to a freight rate for a single commodity being transported between a single origin and a single destination. Contractual freight rates are available if a potential rail movement is sufficiently large, long term, or both. Contracts are confidential and are distributed only to parties to the movement. There is no set rule for the contents of contracts; however, railroads are reluctant to enter into contracts unless the volume of the movement is substantial or the duration is 1 year or more. Rail contracts are available only through the customer service representative.

In some instances, the contract may specify a certain minimum annual volume or a percentage of total shipments to be made under the terms of the agreement. If so, the agreement will require the shipper to certify that the terms of the agreement were fulfilled and the railroad will reserve the right to audit the shipper's documents to verify that the certificate is correct.

Order Cars

The next step in making a rail shipment is to order cars. Six pieces of information are required: the company making the order and its address, the type of car, the commodity to be loaded, the number of cars required, the date or dates when the cars are needed, and the location for empty car delivery.

The easiest way to place car orders is via the railroad Web site; each carrier has an online process for ordering equipment. Car orders can also be placed through customer service departments.

If a shipper is a volume customer, most rail systems will encourage the customer to contact the appropriate car distributor. Car distributors are usually assigned by car type, geographic region, commodity, or all three. The names and phone numbers for car distributors are available from customer service departments or in some cases from the Web sites.

If an empty car has been ordered and delivered and the car is not loaded but returned to the carrier empty, a switching charge will be assessed and collected from the party ordering the cars.

Empty car delivery for loading is not time specific. Railroads make no guarantee of delivery time or quantity of cars. Even when multiple cars are ordered for shipment at the same time on the same bill of lading, there is no guarantee that all cars will arrive at the same time.

One exception exists—the Loading Origin Guarantee (LOGS) program from the BNSF. This program provides a method to guarantee delivery of a specific number of certain types of empty cars on a weekly basis. The program is reciprocal, meaning that a failure to perform on the part of the shipper or the BNSF results in penalties due the other party. Other railroads are implementing equivalent programs.

Receive and Load Cars

After empty cars are delivered, the shipper has 24 hr, beginning at the first midnight after delivery of the cars, to load and release the cars. If multiple cars have been ordered for delivery at the same time, for shipment at one time, and all cars are listed on a single bill of lading, the free time for loading begins at the first midnight after delivery of the final car or on the date for which the multiple cars were ordered. If cars are held beyond the free time allowed, demurrage (see the Demurrage and Furtherance section in this chapter) is chargeable (BNSF 2004a, 2004b, CSXT 2001, KCS 2000, NS 2000, UPRC 2004a).

If multiple cars for loading have been ordered for delivery and shipment at one time, all cars are on the same bill of lading, and the cars arrive piecemeal (i.e., one at a time) before the order date, the shipper may load those cars and hold them until the final car arrives. There is no penalty for holding cars delivered before the order date. If the loaded cars are released and not billed, however, furtherance charges would accrue (see the Demurrage and Furtherance section in this chapter).

Privately owned or leased cars delivered to private tracks can be held for an indefinite period with no demurrage accrual. But if private cars are delivered to railroad-owned tracks or held in storage on railroad-owned tracks, storage charges do accrue.

The consignee, or shipper, is responsible for inspecting empty railcars and for determining their cleanliness and mechanical condition. Railroads will attempt to deliver clean and mechanically sound equipment for loading but will not guarantee or offer a warranty that any equipment delivered is acceptable for loading. The acceptability or lack thereof is the responsibility of the shipper. When a car is loaded and billed, that act is *prima facie* evidence that the car was acceptable for loading. Any damages or loss of lading resulting from leaking doors or holes in the car body are the shipper's responsibility. Any contamination resulting from dirty cars is, likewise, the responsibility of the shipper, not the railroad.

Railcars cannot be loaded to exceed their load limit, which is posted on the side of all railcars along with the maximum gross weight and the tare weight of the car. The maximum gross weight of a car is determined by car construction, specifically its undercarriage. Cars appearing visually identical may have different maximum gross weights and consequently different load limits.

Railroads quote freight rates in two ways: by the carload and by actual weight. If the rate is quoted by the carload, the railroad has no responsibility for weighing except to check for overloaded cars. When the rate is based on actual weight, the shipper may specify that weight if the shipper has a certifiable method of determining actual weight and if the shipper has created a weight agreement with the railroad. If the rate is quoted by actual weight, the weight is determined by the railroad, and the railroad is responsible for weighing the car and determining the actual weight.

Although there is no regulation or requirement that air hoses be reconnected and cars coupled, a shipper is well advised to do so. Connecting air hoses and coupling cars requires time, and if the switching crew is unable to provide this service and complete their assigned work, a shipper may not receive the level of service anticipated.

Managerial Tip 7

When shipping open-topped cars, gondolas, or hoppers, rainfall can cause overloading. Railroads consider only the fact that the car is overloaded, not the reason for the overloading. Consequently, shippers should load cars lighter than their marked capacity to allow for increased weight resulting from possible rainfall. However, if a shipper is certain that an overweight condition is due to rainfall, a sensible source of action is to call for a re-weigh, assuming that the water will drain or evaporate and the weight of the car will return to an acceptable range. An accessorial charge will be made for the re-weigh unless the new weight is within the load limits of the car.

Managerial Tip 8

All freight rate tariffs based on actual weight will specify a minimum weight. Should the railroad be unable to weigh a car, for whatever reason, and cannot determine the actual weight, the minimum weight quoted in the tariff will be the weight for billing purposes.

If a shipper wishes to weigh a car moving under a carload tariff, the railroad will assess a scale charge. More details are given in the Accessorial Charges section in this chapter.

Railcars must not be overloaded. Should the railroad determine from a scale weight that a car is overloaded (i.e., that the car is determined by scale weight to be heavier than the load limit of the car or the gross weight is heavier than the load limits of the track at any point along the route of movement), the car will be stopped and reduced in weight (regardless of location) by the shipper or the shipper's independent agent and reweighed before movement can continue. Penalties accrue for overweight cars (see the Accessorial Charges section in this chapter).

Railcars must be loaded along their centerline with weight distributed evenly along the entire length of the car. Off-center loading is not permitted. Weight should be distributed evenly over each set of wheels. Visual inspection can determine off-center loading; the cars lean to the overloaded side. Off-center cars will derail on curves. When a railroad switching crew notices an improperly loaded car, they will not switch it. Instead they will reject it, and the railroad will notify the shipper that the car is improperly loaded and demurrage will accrue until the off-center condition is corrected. If cargo shifts in a car, even if the car was initially properly loaded, the shipper is responsible for correcting the loading, regardless of the location of the problem. The shipper will incur demurrage charges while the load is being corrected.

Once loading is completed, if the cars have been moved or uncoupled during the loading process, they should be recoupled, their air hoses reconnected, and their hand brakes set on every single car or on at least two cars of a multiple string of cars. Even when cars are parked on an apparently level track, hand brakes should be set.

Loaded cars should not be released without billing. If a railroad pulls cars that have been released but for which billing has not been submitted, the cars will be declared "no bills" and penalties and furtherance charges can be levied.

Regardless of which rail system is used, all acknowledgments and copies of bills of lading and way bills that are created by the railroad and generally available from the Web site should be printed. The person submitting the bill of lading should date and initial all paperwork as documentation in the event of any dispute or improper invoice.

Managerial Tip 9

Release Loads and Bill

Two actions are required after the railcars are loaded: the railcar is released and the transaction is billed.

The following terms relate to releasing and billing of railcars:

- **Consignee:** The party designated on the bill of lading as the entity entitled to receive delivery of the goods (KCS 2004)
- **Consignor:** The party in whose name a railcar is ordered for loading and/or the party furnishing forwarding instructions (CSXT 2003)
- **Commodity:** STCC number or the description of the goods being consigned (UPRC 2004a)

Car release consists of notifying the railroad that the car is loaded and ready to be shipped (pulled). The car can be released verbally, by fax to customer service, or via the Internet. In the immediate future, all releases must be made on the Internet; no verbal or faxed releases will be accepted without an additional charge.

Car release is not the same as billing; car billing, the bill of lading, is the documentation required to ship and route the car. The bill of lading provides the identification numbers for each car being shipped, contains the name of the shipper and the receiver, identifies the commodity being shipped, provides for payment of freight charges, and outlines other pertinent information about the shipment.

Internet filing is either required or soon will be required. It is more secure and the shipper can receive instant confirmation that the bill has been properly completed and accepted. Bills of lading cannot be verbal, but they can be faxed to customer service for an additional fee.

Car release can be included with the bill of lading. Alternatively, the bills of lading may be filed pending release of cars, or filed with a future effective date and time.

Bills of lading should be checked for errors. Any changes made after acceptance of a bill of lading can result in additional charges to the shipper (see the Accessorial Charges section in this chapter).

Monitor and Trace Cars

After the railroad accepts the bill of lading, the shipper should download and print a way bill from the railroad's Web site. The way bill officially documents the shipment. Any changes or modifications of the way bill can incur charges to the shipper, even if changes are minor or insignificant.

All mainline railroads are able to trace shipments on their Web site. There are two forms of shipment tracing available: public and private. A public trace allows the public to trace railcars but gives only the current location of that car. A private trace permits only those party to the shipment to conduct a detailed trace that includes

the history; the current location; the estimated time of arrival (ETA); and, in some cases, the future routing and schedule of the shipment.

The ETA shown on a trace report is, as stated, "estimated." The variables involved in a rail shipment can frequently cause delays of up to several days beyond the scheduled ETA. From time to time, cars get lost, break down, or are bad ordered. Variability in delivery schedules can put the shipment receiver in a difficult situation. For example, should the receiver order unloading equipment in anticipation of delivery and incur extra expense if the delivery might not arrive on schedule, or should the receiver wait until the cars arrive to order equipment and personnel and risk incurring demurrage if that equipment and personnel arrive later than anticipated?

Alternatively, cars may be traced using www.Steelroads.com, a Web site sponsored jointly by a number of U.S. and Canadian railroads. The site can be used to conduct both public and private traces as well as a number of other activities. Users must register with Steelroads and be sponsored by one of the supporting carriers.

Receive Loads

Four options for delivery of incoming railcars are available to the customer receiving loaded cars: *order-in*, *spot-on-arrival*, *keep-full*, and *constructive placement*.

1. **Order-in.** Cars arriving at the switching yard of the delivery carrier will be held there until the customer orders the cars to be delivered. All such orders must be in writing (fax or Internet).
2. **Spot-on-arrival.** Cars arriving for delivery will be placed immediately on arrival, providing there is capacity on the receiving track. No order is required by the consignee; no notice is provided by the delivering railroad.
3. **Keep-full.** When more cars have arrived for delivery than can be accommodated by the capacity on the receiving track, cars will be held in constructive placement by the railroad and delivered as space is available. No order is required by the consignee unless consignee wishes to order-in a specific car.
4. **Constructive placement.** When a railcar cannot be actually delivered because of any condition attributable to the consignor or consignee, the cars will be held on the tracks of the delivering carrier, notice will be sent to the party entitled to be notified, and demurrage will be charged pending instructions.

Immediately after the loaded cars are received, the cars and cargo should be inspected for damage and for integrity of seals on doors and locks if sealed. If damage is found, the delivering railroad should be notified before unloading.

Initial notification may be verbal but should be followed by written communication asking the railroad to inspect the shipment. The railroad should either agree to inspect the shipment or waive rights to inspection. If rights are waived, they should be waived in writing.

If the railroad agrees to inspect the damage, any demurrage incurred while waiting for the inspector is not chargeable to the consignee.

Any notification by the inspecting party of inability or failure to inspect should be recorded along with time of notification and names of the individuals giving and receiving notice. If inspection has not been conducted within a reasonable period, the railroad should be notified again.

If the railroad waives inspection, a neutral third party should inspect the car and its contents, and any report resulting from the inspection should be made part of any claim filed against the railroad. Photos should be taken of any visible damage.

Railcars should be traced daily, not only to find diversions of cars, but to maintain control of the shipment. Cars can be incorrectly routed, lost, bad or derailed, or simply delayed for an excessive period of time. Problems can be addressed by creating a problem log with the customer service department.

Managerial Tip 10

If goods are lost from a bulk shipment in a hopper car and one of the doors is defective, broken, or open, the loss of goods is subject to claim against the railroad for loss of lading. But if the door simply leaks because it is warped or fails to make a tight seal, any claim for loss of goods is credited against the shipper and not the railroad. The shipper, not the railroad, is responsible for ascertaining whether a car is suitable for loading. Determining suitability includes both mechanical condition of the equipment and cleanliness. The act of billing and releasing a railcar is *prima facie* evidence that the car is clean and in acceptable mechanical condition for use (UPRC 2004b).

Lading escaping from an unsound gondola—one with holes or cracks in the bottom or side walls—is credited against the shipper, not the railroad, as previously described for hopper cars.

Loss incurred from a covered hopper with open or leaking “loading doors” might be claimed against the shipper or the railroad, depending on whether the door was properly closed and locked or the locking mechanism was defective. Inspecting the car after arrival can usually determine culpability.

Unload Cars

After the cars arrive at their destination, the consignee has 48 hr of free time to unload the car, with time beginning at the first midnight after the car is received. See the discussion of demurrage for further details about free time and charges for holding cars.

Cars should be completely unloaded and cleaned if they are not scheduled for reloading with identical cargo from the same origin as the shipment being unloaded. Railroad rules require that cars be emptied and cleaned sufficiently so that the next cargo can be loaded without contamination. In practice, however, car distributors generally ask (or the shipper should specify) if clean cars are required. If clean cars are needed and if there is any danger of cross-contamination, the railroad usually cleans the cars before delivery for loading.

Cleaning requires time—time to deliver the car to the cleaning facility, time to clean the car, and time to return the car to the shipper. If empty cars are needed for loading and delivery time is a factor, the shipper should consider cleaning the cars.

Release Empty Cars

After unloading the railcar, the car must be “released empty” to the switching railroad. Although most railroads still accept car releases verbally, the trend, as in the case of releasing loaded cars and billing cars, is toward electronic release using the Internet. Extra fees may be incurred for verbal or faxed releases. The switching railroad will not remove an empty car until it has been released. The exact date and time of the release, not the date and time that the car is actually removed, is the time of record for purposes of demurrage.

Normal operating procedure for U. S. railroads is to give a switch crew written orders based on customer requests and releases

The imposition of demurrage charges on cars being unloaded is one of the most expensive and contentious accessorial charges imposed by railroads. Complete and detailed records are required to contest demurrage charges. A log book in which detailed records of car deliveries and switches is demanded. That log book should record the exact date and time of all switches performed by the railroad and the exact order in which cars are spotted upon delivery.

If newly delivered cars are spotted in front of cars previously delivered, whether or not the new cars impede unloading of the previously spotted cars or not, the cars delivered previously may be declared “off spot,” and demurrage on those previously delivered cars will not begin until the first midnight after the cars have been rearranged in proper chronological order. Declaration of an off-spot condition must be made to customer service and should be followed with written confirmation.

Alternatively, if a switch order specifying a delivery sequence for the cars has been properly given to the railroad and the cars are delivered and spotted incorrectly, all cars spotted incorrectly may be declared, in writing, off spot and demurrage will not begin until the cars are rearranged in the proper order as specified in the switch order.

Managerial Tip 11

received before creating written orders. Normally these orders must be received by midnight, or in some cases by 6:00 AM. In most instances, a switch crew will not remove an empty car unless it has written orders to do so.

If the railroad removes a loaded car in error, the railroad will return the car at no additional expense to the car’s consignee. Carriers will not be responsible for any incidental expenses (for example, expenses incurred when a plant ran out of raw materials) resulting from the accidental removal.

Pay Freight Bill

A freight bill is created by the shipping railroad on the date of shipment. Payment can be made by check, wire transfer, or, in some cases, by credit card. Most Class I and II railroads in voice and accept payment via the Internet.

Payment terms vary slightly among the different carriers, but all demand payment regardless of whether the shipment has been delivered. Most railroad systems charge interest on overdue payments. An unpleasant reality of the railroad collection system is that the payment for services rendered is frequently due before those services have been performed.

The due date for freight bills for cars that have not yet been delivered can be postponed until the date on which delivery is actually accomplished. A railroad may still levy interest for late payment of freight bills, but any such payment of interest can be protested, usually successfully.

Incidental errors on freight bills such as erroneous weights, improper charges per ton, or billing based on a carload rate when a tonnage weight should apply can be corrected on the freight bill. An explanation should be attached and the proper payment rendered in accordance with railroad payment terms. Railroad error is not acceptable grounds for nonpayment of freight bills.

ACCESSORIAL CHARGES

Since deregulation, railroads charge for services rendered in addition to the actual charges of freight from point to point. These charges are called accessorial charges or chargeable services. "Actual placement," for example, means the actual physical delivery of a railcar to an accessible position for loading or unloading or to some other point designated by the consignor or consignee (UPRC 2004c) is an accessorial charge.

Accessorial charges most applicable to the mining industry are

- General rules and charges
- Demurrage and furtherance
- Storage
- Weighing and reweighing
- Overloaded or overweight cars
- Reconsignment and diversion
- Switching

The monetary charges levied for various accessorial services vary between railroad systems and tend to escalate with time. The appropriate tariff for each system should be consulted to determine the effective charge.

General Rules and Charges

Each railroad maintains a set of general rules and charges (BNSF 2001c, CSXT 2002, KCS 2002, CN Railways 2004, UPRC 2004c) relating to those rules. In the past, rule books were available in bound form. Today, rule books are available only on the Internet. The shipper, or railroad customer, who needs a hard copy may print a copy directly from the Web site.

The following Web page addresses include the general rules and charges published by the U.S. Class I railroads:

- BNSF: <http://domino.bnsf.com/website/prices.nsf/PriceRpt?Open&mp>
- CN Railways: www.cn.ca/productservices/chargeableservices/en_KFCchargeableservices.shtml
- CSXT: www.csx.com/index.cfm?fuseaction=assessorialactive
- KCS: www.kcsi.com/pdf/kcs9011.pdf
- NS: www.nscorp.com/nscorphtml/pdf/nsle.pdf
- UPRR: www.uprr.com/customers/ind-prod/pdf/6600cBook.pdf

Of the hundreds of rules included in the above general rules and charges, several of the rules more specifically apply to the minerals industry and are discussed in detail in the following sections.

Demurrage and Furtherance

Demurrage is charged on empty cars being loaded or awaiting loading; on loaded cars being or a waiting unloading; and on any cars being stored, held, or kept out of revenue service by actions of a customer. Demurrage is also charged on any cars "constructively placed" (i.e., cars being held on railroad property awaiting delivery to the customer's facilities).

Demurrage, furtherance, and storage charges apply to railroad-owned equipment on railroad or private property and private equipment when stored on railroad property. Demurrage charges do not accrue on private equipment held on private or leased tracks. A track leased from the railroad is treated as a private track.

Railroads do not compensate owners or lessees of private equipment held or delayed by the railroad. Because railroads do not guarantee any route or delivery date, any expenses incurred by owners or lessees of private equipment are not reimbursed.

Web page addresses for demurrage and furtherance rules and charges follow:

- BNSF: <http://domino.bnsf.com/website/prices.nsf/PriceRpt?Open&mp>
- CN Railways: www.cn.ca/productservices/chargeableservices/en_KFCchargeableservices.shtml
- CSXT: www.csx.com/share/csx/assessorial/forms/docs/CSXT_8100_Demurrage_Provisions_Section_VIII_as_of_122002_REF10286.pdf

- KCS: www.kcsi.com/pdf/kcs6000.pdf
- NS: www.nscorp.com/nscorphtml/pdf/demurrage_faq.pdf
- UPRR: www.uprr.com/customers/demurrage.pdf

Loading Demurrage

Loading demurrage is charged when a customer receives empty cars destined for loading. Time starts at the first midnight after the cars are placed or the midnight of the date for which the cars were ordered, whichever is later. Most U.S. railroads allow 1 day for loading. KCS and CN Railways allow 2 days. Demurrage does not accrue for Sundays and listed national holidays unless demurrage was chargeable for the day preceding.

Table 2 presents demurrage charges for empty cars held for loading or constructively placed awaiting delivery for 1 day where 1 day is allowed for loading.

Unloading Demurrage

Unloading demurrage is charged when a customer receives loaded cars destined for unloading. Time starts at the first midnight after the cars are actually delivered or when notice of constructive placement has been given, whichever is earlier. All U.S. railroads allow 2 days of free time for complete unloading of cars.

Table 3 presents demurrage charges for loaded cars held for unloading or constructively placed awaiting delivery for unloading.

Sundays and holidays are excluded from demurrage unless demurrage is being charged on the preceding day. A list of holidays exempt from demurrage charges is contained in the demurrage rules of each individual railroad.

Furtherance

Furtherance is charged when a car is released without billing by a customer or received by the railroad from another railroad without forwarding instructions. Time starts at the first midnight after the car is received. No free time is allowed for furtherance.

Furtherance charges are levied at the same rate as demurrage charges.

Furtherance is not levied if billing has been properly submitted but the railroad fails to remove the cars. Likewise, furtherance is not levied if the shipper has prepared proper billing and the originating railroad fails to provide the connecting carrier with correct documentation. Either situation is defined as railroad error.

Storage

Storage is a fee charged when either the consignor or consignee requests that an assigned car be stored for an extended period either on or off railroad property. Storage also applies when private cars are held on railroad property.

The primary application of storage is using railcars for mobile warehousing. Storage is common within the plastics or chemical industries but rare in the minerals industry.

Table 2. Demurrage charges for empty cars held for loading where one free day is allowed

Spot Date	Monday	Tuesday	Wednesday	Thursday	Friday	Saturday	Sunday	Monday	Tuesday
Monday	Spot	Free	Debit	Debit	Debit	Debit	Debit	Debit	Debit
Tuesday		Spot	Free	Debit	Debit	Debit	Debit	Debit	Debit
Wednesday			Spot	Free	Debit	Debit	Debit	Debit	Debit
Thursday				Spot	Free	Debit	Debit	Debit	Debit
Friday					Spot	Free	Free	Debit	Debit
Saturday						Spot	Free	Free	Debit
Sunday							Spot	Free	Debit

Notes:

- “Spot” means the car was delivered before midnight.
- “Free” means no demurrage time is charged.
- “Debit” means demurrage is charged.
- No offsetting credits are allowed for cars delivered for loading.

Examples:

- Cars delivered on Monday, Tuesday, Wednesday, or Thursday are allowed 1 day of free time. All additional days are charged demurrage.
- Cars delivered on Friday receive Saturday and Sunday as free days. Monday would be a day of demurrage.
- Cars delivered on Saturday receive Sunday and Monday as free days. Demurrage does not accrue for Sunday, and Monday is the free day.

Table 3. Demurrage charges for loaded cars held for unloading where one free day is allowed

Spot Date	Monday	Tuesday	Wednesday	Thursday	Friday	Saturday	Sunday	Monday	Tuesday
Monday	Spot	Free	Free	Debit	Debit	Debit	Debit	Debit	Debit
Tuesday		Spot	Free	Free	Debit	Debit	Debit	Debit	Debit
Wednesday			Spot	Free	Free	Debit	Debit	Debit	Debit
Thursday				Spot	Free	Free	Free	Debit	Debit
Friday					Spot	Free	Free	Free	Debit
Saturday						Spot	Free	Free	Free
Sunday							Spot	Free	Free

Notes:

- “Spot” means the car was delivered before midnight.
- “Free” means no demurrage was charged.
- “Debit” means demurrage was charged.
- If a car is released on the day it is delivered or on the first free day, one day of credit is given against chargeable demurrage.
- Credits are not transferable between months.

Storage is not demurrage. Cars are stored, and released from storage, by written order from the party to whom the cars have been assigned, or in the case of private cars, the car owner or lessee.

Storage is charged per diem. Additionally, switching is charged for putting cars into and taking cars out of storage.

Storage charges are not levied on private cars stored on private tracks although switching charges are applicable for moving cars into and out of storage.

Storage charges are usually less than demurrage charges.

Weighing and Reweighing

Loaded railcars are weighed for two reasons. First, the tariff is based on actual weight and the railroad must determine the actual weight using certified scales. Second, the cars are weighed to see if they are overloaded.

If the freight rate is based on actual weight contained in the car, the carrier is responsible for determining weight.

If the shipper disagrees with the weight determined by the carrier, the shipper may request a reweigh. If the reweigh shows that the original weight was within a certain specified tolerance, the shipper will be assessed a reweigh charge.

If a reweigh reveals that the original weight determined by the carrier was incorrect by the specified tolerance, the documentation and billing on the car will be corrected to reflect the newly determined weight and the shipper will not be assessed a reweigh charge.

Overloaded or Overweight Cars

Overloading railcars is inherently unsafe. With the encouragement of the STB, railroads are assessing high monetary charges for overloads or overweights.

An overloaded car is defined as a car loaded in excess of its load limit, which is stenciled on the side of the car.

An overweight car exceeds the load limits placed on a route that the car is scheduled to take.

When an overloaded or overweight car is identified, the action taken by the carrier will depend on the weight of the car. If the car is less than 2,000 lb overweight, in most cases it will be allowed to continue in transit and a minimum penalty will be assessed. If the car is more than 2,000 lb overweight, the car will be stopped, an overweight penalty will be assessed, and the consignor will be ordered to take corrective action, which entails removing excess

The excessive penalties levied by the rail carriers for overloads and overweights justify whatever action is required to avoid them. Open-top cars should be loaded to account for potential rainfall. Consideration should be given to loading cars lighter than their stenciled net weight to provide a safety factor against overloads.

Managerial Tip 12

lading. That excess lading may be loaded onto another railcar or carried to a proper disposal site.

The railroad's overload department can supply the names of local contractors qualified to remove the excess lading. Contractors exist in virtually every large city and metropolitan area. Charges levied by contractors to lighten an overweight car are frequently exorbitant because local contractors recognize the vulnerability of the shipper and the high cost of mobilizing a crew from a distant location.

If the excess lading is placed in a second railcar, that second car may be billed at the price from the point of origin where the excess lading is loaded and may be billed as a fully loaded car.

In addition to the overweight penalty, switching charges to and from the point of corrective action may be levied, along with demurrage charges for time required to remove the excess lading. Finally, the railroad may levy a reweigh charge for weighing the car a second time.

Reconsignment and Diversion

A diversion is any change in any billing or shipping document that changes the route or destination of a previously billed railcar.

Typical diversions are changes in destination, route, or location of consignee. A diversion requires that physical action be performed on the railcar to alter its route or destination. A reconsignment is a change in any billing or shipping document that does not change the route or destination of the railcar.

Typical reconsignments are changes in the

- Name of consignor
- Name of consignee
- Commodity code (STCC)
- Party paying the freight bill
- Payment method from "prepaid" to "collect" or reverse

Typical diversions are

- change of origin
- change of destination
- change of route

Reconsignments or diversions must be accomplished in writing on company letterhead and will not be accepted if any of the following are true:

- The railcar has reached its destination.
- The railcar has been delivered to another carrier.
- The railcar has been blocked (connected) into a train that will carry it to its final destination or interchange point with another carrier.

Although railroads will usually make a best-effort attempt to execute a diversion, they will not guarantee, nor be responsible for, executing the diversion at a specified time or place.

The party requesting the diversion or reconsignment is responsible for paying charges levied by the railroad. Normally a

diversion charge is substantially more expensive than a reconsignment charge, because the diversion requires physical action on behalf of the railroad.

Multiple car shipments tendered on a single bill of lading from a single shipper at a single origin to a single consignee may not be separated by diversion.

If a reconsignment or diversion order has more than a single change, all changes will be executed and only one charge will be levied—the highest applicable charge.

Empty cars returning from a destination may be diverted at no charge if no alteration of route is required.

Switching

Switching is moving a railcar from one location to another. Line-haul or cross-country movements are excluded from the definition.

Five types of switching are defined in railroad rules and regulations: reciprocal, intraplant, intraterminal, interterminal, and intermediate (see, for example, UPRC 2004d).

Reciprocal Switching

A reciprocal switch is the delivery of railcars by a carrier that does not participate in the line haul and for which the switching carrier has agreed to provide services for a fixed price. When a carrier delivers a railcar to its destination but another carrier serves the customer to which the car is to be delivered, the switch performed by the second carrier is a reciprocal switch. A reciprocal switch charge includes the empty delivery and the removal of the load, or the reverse.

A reciprocal switch charge is normally included in the rate quote. Public tariffs issued by each carrier specify the total sum, which can apply to reciprocal switching. The specified switching allowance is the total allowed for the entire movement, including switching at both ends of the movement.

Reciprocal switching is not available for all customers at every station. Each station will have switching limits defined by the carrier at that station. A reciprocal switch is not available to customers located outside the switching limits. A switch to that customer will require a line-haul charge.

Some industries located within the switching limits defined by a carrier may be closed to reciprocal switching. A carrier uses closure when it can perform both the line haul and the local switch and wishes to deny the line haul to any other carrier that could perform the line haul but not the local switch.

Switching beyond the switching limits of a carrier will entail payment of additional switching charges. These additional charges can be found in the switching charges for each carrier.

Intraplant Switching

An intraplant switch is moving empty or loaded cars from one track to another, or from one point to another on the same track, within the confines of the same plant or mine site, without leaving the tracks of the plant or mine site.

As an example, if a mine site had multiple tracks and needed cars switched from one track to another, or needed the cars on a certain track rearranged, an intraplant switch would be required.

Charges are assessed for each car moved with an intraplant switch.

Intraterminal Switching

The term intraterminal switching means switching from one location to another, other than intraplant switching, within the switching limits of one station of the same railroad.

Continuing the above example, if the mine site and preparation plant were located on the same railroad, at the same station, but

at different locations, a switch between the two locations would be an intraterminal switch.

Interterminal Switching

Interterminal switching means switching between one railroad and another within the switching limits of the same station or industrial district.

Again, as in the previous example, if the mine site and preparation plant were located on two separate railroads but within the switching limits of the same station or industrial district, a switch between the two locations would be an interterminal switch.

Interterminal switch charges are normally more expensive than intraplant or intraterminal switch charges and are assessed for each car switched.

Interterminal switch charges will be assessed by both railroads participating in the switch.

Intermediate Switching

Intermediate switching means a switch made by a railroad between the interchange tracks of one carrier and the interchange tracks of another carrier within a station's switching limits. The intermediate switching railroad neither originates or terminates the shipment nor receives a line haul for the shipment.

If a line-haul shipment was being made using two separate carriers and the two carriers did not directly connect at the interchange station, an intermediate switch by a third carrier would be required.

For example, at Baton Rouge, Louisiana, if a line haul were made on the KCS for a UPRR switch, the IC (CN Railways) railroad would be required to make an intermediate switch because the KCS and the UPRR do not directly interchange.

Interchange switch charges are normally included in the reciprocal switch charge, which is included in the line-haul charge.

CONCLUSION

The importance of railroading to the industrial minerals industry cannot be minimized. Interstate railroads transport a significant percentage of the mineral commodities moved in the United States.

During the past era of regulation, railroad transport was a simple matter. The simplicity demanded by governmental regulation, however, almost destroyed the railroad industry in the United States. Bankruptcy and insolvency were immediate threats to the entire industry.

Passage of the Staggers Act in 1980 freed the railroads from most governmental regulation, permitted multiple mergers of rail systems, and resulted in six mainline carriers in the United States. Each of the six holds monopolistic hegemony over certain regions of the country.

Antiquated work rules and inflexible management, both vestiges of the era of governmental regulation, continue to hinder effective operation of the railroads.

Railroads have been unable or unwilling to expand their infrastructure to meet a continuing expansion of business resulting from the general growth of the economy of the United States. Specifically, this failure to improve infrastructure has created significant difficulties for the railroads and for the customers they serve as the United States recovered from the recession of 2001–2002. Many attribute this failure to an insufficient rate of return on investment, but an equal number of railroad critics claim that the failure is one of management and that return on investment for railroads could be at an all-time high.

Unless U.S. railroads can improve their performance and control costs, government re-regulation is an eventuality. Some critics of

the railroads believe that the rights-of-way, now owned by the operating carriers, should be separated from the carriers and turned into common carriers, open to any and all operators capable of meeting safety and operational rules and regulations. Needless to say, the U.S. railroad industry vehemently opposes any such re-regulation.

Recent price increases that exceed the price increases of industrial or consumer goods, however, would lead the independent observer to conclude that the railroad industry has recognized its monopolistic status and that it is starting to take advantage of that position. The future of U.S. railroads will depend largely on their response to the realization that they are a monopoly.

What course the industry will take is uncertain. Will the railroads of the United States grow and recapture much of the business lost to interstate trucking or will the railroads continue to transport a smaller percentage of general freight until they become noncompetitive and lose the general freight business completely? Abandoning passenger service, small-parcel delivery, and less-than-carload shipments to competitors is history. Now, railroads telegraph their disinterest in single-car or occasional shipments, or both, by denying a supply of railcars or by simply providing such poor service that the shipper is forced to use an alternative mode of transportation, regardless of cost.

In any case, railroad transportation will continue to be overwhelmingly important to the industrial minerals industry. Except in those areas where water transport is available, rail transport is the only competitively priced transportation available. Whether this situation continues into the future will depend solely on the reaction of the railroads to the new economics created by their monopolistic status.

Road Transportation of Industrial Minerals

Paul Moore

Hauling bulk industrial minerals by rail and ship is unmatched for moving large volumes over long distances. Road transport, however, remains an equally important transportation mode for mineral movements throughout the world. Trucking offers convenience, flexibility, low cost, and versatility, giving it distinct advantages over rail or water transport in many situations, despite the fact that it lags behind in terms of fuel efficiency and emissions.

In a 2003 report, the American Association of State Highway and Transportation Officials (AASHTO) stated that in 2000, trucks moved 78% of U.S. domestic freight tonnage (st), generated 60% of its short ton mileage, and accounted for 88% of its dollar value, the highest percentage in each category. Trucks moved 11 billion st, valued at \$9.5 trillion, over 2.6 trillion short ton-miles in 2000. Trucking movements are expected to grow to 17,296 million st by 2020, an increase of 62%. Short ton-miles by truck are predicted to grow to 4,174 billion in 2020, an increase of 58%.

Rail moved 16% of total domestic freight tonnage in 2000, second to transportation by truck. Rail movements tended to be longer in distance than truck movements and therefore accounted for a proportionately higher share (28%) of short ton-miles. Rail movements also tended to involve lower-value commodities than truck movements, so rail represented a proportionately lower share (6%) of total domestic freight value. Rail moved 2 billion st valued at \$600 billion over 1.2 trillion short ton-miles in 2000. Water (river barges and coastal and lake steamers) moved 6% of tonnage, 15% of short ton-miles, and 1% of value.

This truck dominance is also seen in more specific statistics for industrial minerals shipments. According to the U.S. Geological Survey (USGS), of the total industrial sand and gravel produced in the United States in 2003, 64% was transported by truck from the plant to the site of first sale or use, with only 35% transported by rail and 1% by other methods. These figures reflect the fact that, specialty ground silicas aside, the vast majority of the sand and gravel produced in the United States is used domestically at consumption sites located relatively close to the producer. Certain commodities, particularly those shipped in large bulk volumes for international export, such as borates, soda ash, and potash, are largely moved by rail to ports, but trucks may still form part of the logistical chain.

Trucking comes into its own when shorter distances and smaller volumes are involved. Indeed, most industrial minerals delivery routes from a mine or plant to the final customer involve some kind of road transport. This covers everything from the entire

route to the final leg to the customer from a port or warehouse storage area or the initial journey to a port or rail-siding stockpile. Intermodal movements are also common, such as the transport of steel ocean containers by a mixture of road and rail.

This is not to say that trucking is restricted to short-distance haulage. Some industrial minerals are trucked long distances, particularly in developing countries and where an efficient, regular rail freight service does not exist. The scarcity of the occurrence of a particular mineral worldwide may also mean that a 500-km or even 1,000-km truck haul is still economic.

The challenge for the producer and consumer is finding out what works best economically for their particular logistical path, taking into account issues such as practicalities of volume, location, required flexibility of supply, in-place infrastructure, distance, and the environment.

This chapter reviews the main reasons why trucking is still the mainstay of the industrial minerals industry, and gives examples of global trucking scenarios for a variety of industrial mineral types.

PRACTICALITIES OF VOLUME

The largest volumes of minerals over the longest distances move by ship and rail, simply because it is almost always far more efficient and cost-effective (particularly in terms of fuel consumption) to do so. A single railcar may carry 90 or 100 t and a unit train may consist of 100 railcars in some cases, such as the railing of soda ash by Union Pacific from Green River in Wyoming to Portland, Oregon, and more recently to Longview, Washington, for export to Asia. This type of volume movement—up to 10,000 t in one train—across such a long distance is simply impractical when it comes to truck transport.

Many of the world's key industrial minerals are produced in small mining operations, however, with low-cost trucking the main form of transport. China is the key example of this, where for minerals such as barite, fluorspar, magnesite, bauxite, and talc, most of the actual mines are very small, and their production is trucked to a regional stockpiling area such as a railhead for onward transport to a port for export. For example, much of the production of white filler barite is near Guiyang City in Guizhou Province. From there, white barite from numerous small mines is trucked to railheads in Nanning, Guangxi Province, where the material is railed to southern Chinese ports for export. Similar logistical routes are used in other Chinese provinces for other minerals.

Figure 1. Two transportation options for GCC in China—(A) Imerys uses 300-t barges for some shipments from its Nanling operation (courtesy of Tom Grow for Imerys); and (B) the truck tankers are loading GCC at the operations of Sunny Stone Industry Co. Ltd., also in Anhui Province. Sunny Stone produces a range of lump, chippings, and powders for various customers, including Asia Pulp and Paper's Dagang mill (courtesy of Sunny Stone).

Although trucking in China is cheap, it is not without its obstacles. In May 2004, the Chinese government implemented new highway laws strictly enforcing restrictions on truck gross weight. Through the country's massive drive for infrastructure improvements, China has discovered that the rapid deterioration of its roads has been partly caused by years of wear from overloaded trucks. To keep freight costs down, and swiftly move large volumes, it has been standard practice in China for suppliers of materials and goods to exceed the designed load specifications of the trucks they use. Typically, a 25-t truck would receive a load of 45 t, for a freight rate of, for example, \$25/t from mid-China to Xingang port. The new load-limit law meant that such loads had to be reduced, thereby increasing freight costs and sometimes delaying transport of the material to port. If a truck is detected as overloaded, it is confiscated and the driver is briefly jailed. This, together with railcars being tied up in iron ore and coke transport, has caused severe shortages of mineral stockpiles at ports that are already seeing major delays and demurrage fees because of ocean shipping congestion.

LOCATION

Location means everything to the economics of industrial minerals. Many of the world's industrial minerals operations are in remote parts of the world, far from any rail siding or port and often in hilly terrain. Trucking is the first and only option, whether all the way to the point of consumption or to the nearest available rail or water transport point.

Many examples exist of very long distance shipments of minerals by truck. In Brazil, Mineracao de Amianto SA (SAMA), one of the world's largest chrysotile producers, trucks its product some 1,600 km from the Cana Brava mine to the port of Santos. New vermiculite producer IBI Corp. trucks flake vermiculite some 800 km from the Mbalé District in Uganda to the port of Mombasa in Kenya.

For wide spread, lower-value minerals shipped in moderate volumes to local consumers, trucking is the most practical option. Good examples are regional lime and limestone operations trucking product to consumers in the same area such as carpet manufacturers, glass plants, and sugar factories.

Other areas are simply too remote for trucking to be feasible. The potential for the extensive lithium, barium, strontium, potash, and magnesia reserves of the Qaidam Basin in China's Qinghai Province has been talked about for years, but their remoteness has limited development until now. The construction of the 1,142-km Qinghai-Tibet Railway is scheduled for completion in 2007, and the Chinese government hopes it will open up the area and its mineral resources.

On the other hand, if a consumer is in a relatively built-up area, often no room exists for a new rail spur, even if the capital exists to build it. Sometimes inland waterways can be used, as in the case of Imerys's Nanling operation in Anhui Province, China (see Figure 1A), where barging is used to transport ground calcium carbonate (GCC) slurry, but generally truck is the only option in more congested regions (Figure 1B). Likewise, barging is used extensively to transport minerals down the Rhine from the ports of Rotterdam, Antwerp, and Amsterdam to reach consumers in western Germany.

INFRASTRUCTURE

Although it overlaps, to some extent, with "location is important," infrastructure is concerned more with available capital and the economic worth of making major investments when considering the return on mineral sales. If the mine or processing plant is not located close to a mainline rail siding, the costs involved in constructing a rail spur are considerable. Similarly, smaller producers and consumers of minerals may not have the loading and unloading infrastructure in place to handle large, bulk shipments. The available silo or

Courtesy of Industrial Minerals.

Figure 2. Trucking is widely used to transport industrial minerals in Turkey. The Calmag truck (left) is being loaded with caustic calcined magnesite big bags for export. This is trucked to a nearby rail siding at Tavsanlı where it is transferred to railcars. The photograph on the right shows a truck delivering sodium feldspar to Kaltun's bulk storage and homogenization site near Gulluk port, in southwest Turkey.

warehouse space will also determine the nature of transport used. Truck transport still requires investments such as overhead bulk silos and a weighbridge, but the cost involved pales compared to the cost of a rail set-up.

Rail systems also vary in extent, quality, and efficiency throughout the world. In France, which has limited inland waterways and what some companies consider an "inconvenient" rail freight system, trucks dominate mineral transport. For example, leading world GCC producer Omya AG conducts virtually 100% of its GCC freight by truck in France. In the United Kingdom, kaolin shipments for key domestic accounts are made by rail, such as kaolin slurry railed to UPM's Caledonian paper mill in Irvine, Scotland. The bulk of the kaolin is exported from the Cornwall ports of Fowey and Par, however, so dry bulk kaolin is trucked there from Irvine for stockpiling at the docks and loading onto ships. Imerys operates a fleet of 50-t articulated tipper trucks for this purpose.

Inefficiencies in national rail systems may also mean rail cannot be used to its potential despite the existence of the basic infrastructure. An example of this is Turkey, now one of the world's most important industrial minerals producers and a global player in sodium feldspar, borates, and magnesite supply. The Turkish rail system, developed under Atatürk's rule, is extensive. A lack of investment over the years, however, together with a powerful domestic trucking lobby, has meant that much of the country's mineral production now uses truck despite the existing rail network. Figure 2 shows delivery of sodium feldspar from a mining operation to the Kaltun processing, storage, and blending site near Gulluk port, where the finished material is trucked again a short distance for loading onto bulk vessels for shipment to the Spanish and Italian tile industries.

CONSUMER SIZE

Just as the size of the mineral producer affects whether trucking is used, so too does the size of the consumer. Large mineral operations will often ship material by both truck and rail, with some of the larger accounts served by rail and the more numerous smaller accounts served by truck. For example, key accounts for large, bulk lime operations supplying the steel and flue-gas desulfurization (FGD) industries may be served by multiple 100-t railcars, with the smaller accounts served by trucked 1-t big bags or 25-kg sacks wrapped in plastic on pallets. In the industrial sands market, large

shipments to foundry and glass consumers may be made by rail, with materials for smaller accounts such as filtration and sports/leisure shipped by truck.

ENVIRONMENT

Where a choice exists between road and rail, the impetus has increasingly been to move minerals traffic to rail because of the savings gained in terms of emissions, and noise, safety, and traffic levels on public roads. Moving to rail has the additional positive effect of improving the public image of a mining or processing operation, because the movements become far less obvious to the public if made off the roads. Equally, in terms of planning applications for new mineral operations, getting permission to allow heavy mineral truck traffic on a well-used public road is often the most difficult hurdle to overcome.

In an article in a Vermont newspaper (*The Rutland Herald*, August 23, 2004), Bruce Edwards reported that progress has been made for a rail spur to Omya's marble-mining operation in Middlebury, Vermont. The proposed rail spur would eliminate the marble trucks that currently use Route 7 between Middlebury and Florence, where Omya's huge GCC plant is situated. This single, \$20 million, 3-mile rail spur between the Middlebury marble quarry and the main rail line would take 75,000 truck trips per year off the road.

COST AND OWNERSHIP

Large companies dominate rail and shipping freight services. In the United States, the so-called Class 1 carriers such as Union Pacific, CSX Transportation, BNSF Railway, and Norfolk Southern dominate. In Europe, a few rail freight carriers tend to dominate trade in each country, such as Railion in Germany, Société Nationale des Chemins de Fer (SNCF) Fret in France, and English Welsh & Scottish Railway Ltd. (EWS) in the United Kingdom. This situation is less marked in ocean shipping, where of ten numerous brokers and options are available, but it depends on the particular route concerned.

By contrast, trucking tends to suit much smaller companies with a small truck fleet. Mineral producers, particularly in developing countries, often use individual private-owner operators. In the United States, small haulage companies that combine a group of owner-operators are the most commonly used. For example, the Alabama-based lime company Cheney Lime & Cement lists no

fewer than 12 trucking companies that handle lime from its plant in Shelby County. By contrast, it is served by only one rail carrier—CSX Transportation—which owns and operates the track rights in that region.

In many cases, the industrial minerals supplier dominates the business of the trucking company—in contrast to rail, where industrial minerals often form only a fraction of the overall rail company revenues. For example, the Association of American Railroads (AAR) lists nonmetallic minerals at 7.4% of its Class 1 tonnage traffic in 2003, well behind coal at 43.6%. This means that the industrial minerals companies are farther down the list in the priorities for the railroads, which may have only a few people responsible for minerals marketing in the whole group. The situation becomes even more complex on rail when a relatively small volume is being moved across an area covered by several different rail companies—ultimately this all adds to costs for the mineral supplier.

Rail service and railcar reliability have become major issues in the U.S. industrial minerals industry in 2004–2005, particularly on the West Coast, where routes have been affected by heavy rain and floods. In these types of situations, the versatility of the truck is apparent. By contrast, often a particular minerals operation may represent the main business for one or several trucking companies. U.K. barite producer M-I Drilling Fluids UK uses Barhaul, a local haulage company, to transport its drilling-grade barite products from the underground mine in Aberfeldy, Scotland, to the grinding facility near Aberdeen. This is a symbiotic partnership in which the M-I contract accounts for the majority of Barhaul's business, and it is useful for M-I to have a local company focused on delivering the best service to its main client.

This is not to say that large trucking companies do not exist. For more specialized movements such as volatile and reactive materials or fine-grained powdered materials, special vehicles are often needed. Examples include Norbert Dentressangle, which ships large quantities of soda ash and other mineral powders in Western Europe using more than 900 tanker trucks.

Larger minerals producers may also own or long-term-lease their trucking fleet. Ameri-Co Carriers is a wholly owned subsidiary of Amcol International Corp., and the majority of its business is the transport of Amcol's natural sodium bentonite-based products such as cat litter and environmental liners. The company, however, also has a growing base of outside customers. In Europe, silica sand specialist SCR Sibelco and its partner companies throughout Europe operate large tanker truck fleets. Larger contracts may be handled by the customer, such as the railing of dolomite from Lhoist's operations in Belgium to consumer Nedmag in Veendam, the Netherlands.

TRUCK TYPES

The range of vehicle types used to transport industrial minerals varies by volume and the nature of the material. Simple bulk tipper trucks are often used for nonreactive, free-flowing materials such as silica sands and limestone for basic industrial uses. Slurries such as GCC and kaolin are transported in special tank trucks into which the material is pumped at a tank farm and unloaded in a similar way at the consumer point such as a paper mill.

Courtesy of Triple Crown Services Company.

Figure 3. The Triple Crown RoadRailer is one type of intermodal solution. The RoadRailer's unique air-ride system lifts the trailer gently as it is backed over the bogie for attachment. Once the bogie is in place, the air system lowers the trailer and lifts the tires off the tracks.

Other volatile materials such as lime or finely powdered materials are shipped in pneumatic silo trucks equipped with a blower to blow the material into the consumer storage silo (e.g., at a precipitated calcium carbonate plant). Bagged minerals, including pallets of small bags and larger bulk bags, are also trucked, but generally on flatbed trucks or inside an ocean container.

One trend in recent years has been combining truck and rail transport in so-called intermodal routes. This more commonly involves transferring ocean containers from rail to truck or vice versa, but can also involve transferring loose bulk or big bags. This is common in situations where the mine and plant of a small producer are not served by rail and the rail volumes are insufficient to justify investment in a rail spur, even though there is a rail siding relatively close by. Instead, material is loaded onto trucks and transferred to the railcars at the siding.

Larger players have invested in intermodal hubs along the most heavily used parts of the logistical network (Figure 3). In the U.S. market, Solvay serves customers requiring less than railcar volumes using 12 bulk rail-to-truck terminals. These provide a reliable source for customers and a nearby supply position to deal with urgent product requests.

Ship and Barge Transportation of Industrial Minerals

Barry Parker and MID-Ship Marine Inc.

INTRODUCTION

This chapter summarizes the waterway and marine transport logistics of industrial minerals. Transportation is a critical element of the minerals business because deposits of raw materials may be in locations that are widely separated from where they are processed (Barker and Austin 1995; Barker 1997; Barker 2004; Barker and Harben 2004). Processing facilities may in turn, be oceans away, or perhaps miles away along a river, from industrial consumers further down the logistics chain. Transportation costs are often the single most crucial element in determining the ultimate profit or loss—the basic feasibility—of a specific mineral operation and associated transportation movement.

Ocean transportation in deep-sea vessels is discussed in the same chapter with barge transportation along U.S. inland-river and intracoastal-waterway systems because they are interrelated.

Topic Definition

This chapter covers the waterborne transportation of industrial minerals in bulk (see the glossary at the end of this chapter for definitions). The focus is on international deep-sea shipping as well as on U.S. domestic movements of industrial minerals by barge. The chapter also discusses fungible industrial minerals that move in dry-bulk carriers, sometimes as full cargo and sometimes as parcels. *Parcels* are multiple consignments transported on the same vessel, albeit with integral physical or suitable artificial segregations to prevent commingling of the shipments.

History

The industrial minerals business has evolved along with advances in transportation capabilities. The availability of economical ocean and barge transportation has enabled more distant sources of industrial minerals supply to be exploited and economically transported to processing or consuming locations. Industrial minerals are often found hundreds or even thousands of miles away from facilities where they are processed, and water transportation often binds the individual links in industrial minerals supply chains.

Economies of scale are possible where supply chains can handle larger vessel sizes such as *Capesize* behemoths capable of hauling 180,000 or even 300,000 t of coal or iron ore. Few industrial minerals, however, move in vessels larger than *Panamax* size. For this reason, the emphasis in this chapter is on smaller vessels, known as *Handysize* or *Handymax* size, capable of transporting 25,000 to 50,000 t of material.

Classification and Industry Structure

Maritime transportation can be segmented very broadly according to trades and types of vessels:

- *Dry bulk*: These vessels transport industrial or agricultural raw materials and semiprocessed materials primarily in bulk. They range widely in size from barge (transporting typically 1,500 t of materials) up to the huge *Capesize* ships that are too big for most ports. Industrial minerals typically move on dry-bulk vessels, often as parcel shipments. The service speeds of self-propelled deep-sea vessels typically range from 10 to 15 knots.

Within the dry-bulk category, certain vessel types and sizes predominate, as shown in Table 1.

- *Container/liner*: Goods packed in ISO standard cargo containers, typically 20 ft (6.058 m) or 40 ft (12.192 m) long, are transported by vessels specifically configured for carrying containers. Industrial minerals are sometimes containerized. Container vessels generally operate in “liner trades,” with widely published regular schedules known well in advance. Rates are also negotiated in advance and would be included within a confidential service package.
- *Liquid bulk (tanker)*: Tankers carry bulk crude oil, refined or intermediate petroleum products, industrial chemicals, and oils derived from agricultural processing. Such vessels are not suitable for industrial minerals, except where grain is shipped in tankers (and the cargo is loaded and discharged by spout or pneumatic equipment).
- *Specialized industrial*: These are highly specialized vessels, built specifically for transporting particular commodities. Examples include liquid-gas carriers, livestock carriers, and refrigerated cargo carriers (for meats, fruits, and vegetables). An overlap occurs with industrial minerals, where vessels are designed to transport ores or materials in self-unloading bulk carriers or in slurry form.
- *Cruise/passenger*: The passenger shipping segment is a highly visible sector of the market but is not relevant to the transportation of industrial materials.

Within dry-bulk shipping, a deep-sea (ocean-going) component exists along with a domestic barging component. The deep-sea shipping industry is mainly an international business, whereas the U.S. inland-river-barging industry is domestic. Both are subject to technical regulation by their respective *Flag State*, which is the

Table 1. Bulk vessel types and characteristics with typical Mississippi River barge dimensions shown for comparison purposes

Common Vessel Types	Typical Deadweight, tons and meters of draft	Typical Dimensions, length by beam	Typical Cargo Handling Gear
Barge	1,500 t on 9 m	59.44 m × 10.67 m	None, gearless
Handysize	26,000–33,000 t on 9.5–11 m	165–185 m × 23–29 m	4 or 5 cranes at 25 t each
Handymax	45,000 t on 11.6 m	186 m × 30.5 m	5 cranes at 25 t each
Super Handymax	55,000 t on 12.26 m	190 m × 32.26 m	5 cranes at 30 t each
Panamax	75,000 t on 14 m	225 m × 32.26 m	Usually gearless
Capesize	172,000 t on 17.75 m	289 m × 45 m	None, gearless

country where the ship is registered and which is therefore responsible for enforcing the applicable international conventions or domestic laws and regulations as they affect vessel operations.

Most countries maintain “national flag” vessels to handle their domestic- and government-sponsored movements as well as any military requirements. Deep-sea manned vessels must meet requirements of the SOLAS (Safety of Life at Sea) Conventions. Vessels must be inspected annually by their Flag States. Often, authority for such inspections is delegated to *classification societies*, which are international organizations that employ networks of surveyors and inspectors throughout the world who examine vessels. Vessels are also subject to detailed physical surveys, which are required every 5 years and usually coincide with out-of-the-water dry dockings.

For barges in the U.S. domestic trades, the American Bureau of Shipping handles technical regulation, enforcing regulations promulgated by the U.S. Coast Guard.

After the terrorist attacks on the United States on September 11, 2001, a new set of regulations concerning security of vessels and ports or shore facilities were added to requirements facing both shipowners and terminals.

Despite the array of technical, safety—and now security—regulations facing the industry, the bulk-shipping segment is not subject to economic regulation. Freight levels rise and fall depending on the interaction of cargo demand and vessel supply and are freely negotiated. Bulk shipping is sometimes described as the last bastion of the free market.

The shippers of cargo, who charter vessels (and are thus known as *charterers*), rely heavily on the free market for their supply of vessels. The supplier of the shipping tonnage may be the actual owner, or the supplier may be an operator who takes a vessel on charter from the primary owner and then resells space on the vessel to cargo owners.

Statistics

Freighting of industrial minerals is a subset of a much larger marketplace in dry-bulk shipping. The dry-bulk marketplace comprises dozens of subsectors representing the market in each commodity. The vessels in the marketplace are flexible and able to handle many cargo types, and thus they can respond to market opportunities among multiple subsectors and evaluate the most attractive daily returns. The industrial minerals trades form a small subset, estimated to be less than 20% of the total tonnage.

Table 2 shows the growth of the major commodity trades (in millions of metric tons). Major bulks are iron ore, coal, grains, bauxite and alumina, and phosphate rock. These major bulks move on dry-bulk carriers, but the total tonnage includes commodities that may move on specialized vessels. Tables 3 and 4 show the growth of the dry-bulk shipping fleet.

The balance of overall supply and demand over a multiyear time horizon determines the overall levels of freight rates in the marketplace. Vessel demand is also subject to short-term economic

influences, weather, seasonality, and market timing. In addition, technical, structural, and physical disturbances—mechanical breakdowns, inefficiencies, or plant production problems—are factors. Supply chain influences to or from the plant (such as rail, truck, or barge shortages) can and will cause delays and congestion—which, in turn, will affect overall vessel supply. Demand can be very volatile, especially where a number of charterers may be competing for available vessels. Even in the industrial trades, scheduling considerations can heighten this volatility. For example, where commodities are sold under yearly contracts, there may be a rush to move material just before the end of an expiring contract. Because of the many raw materials moved in bulk carrier vessels, shippers of industrial minerals may face rates that are determined exogenously.

Vessel supply is less flexible, involving capital investments in long-lived assets. The economic life of bulk carriers is typically 20 to 25 years. In poor freight markets, the owner may decide to scrap the vessel before the end of its economic life. In strong freight markets, owners may decide to invest in extra maintenance and repair that will enable the vessel to continue trading beyond the 20-year mark.

The interaction of semi-fixed supply and rapidly shifting demand brings about volatile freight markets. Strength in the sector from 2003 to 2004 resulted from a sharp increase in demand in the face of little new tonnage on order for vessel supply. Strong demand from countries such as China and India (with their huge populations) has been and will be a major factor that makes demand forecasting difficult, if not impossible. The strong freight market did lead to reduced scrapping and more vessel orders, but new tonnage is typically not delivered until 18 to 24 months after an order is placed.

TECHNOLOGY

Vessel Configurations

Most of the vessels involved in the industrial minerals trades have the generic term of *bulk carriers* and are Handysize and Handymax- or Super Handymax-size vessels, with Panamax-size vessels used as the demand increases (the latter depend on port infrastructure and restrictions). Unlike general cargo vessels with multiple decks and obstructions, bulk carriers have cavernous holds and large hatches that provide loading and discharging equipment substantial access throughout the holds. Bulk carriers can also be strengthened so that they can take full loads of dense or heavy cargo in alternate holds without placing undue stresses on the vessel's structure. As a matter of economic practicality, vessel owners will build versatile vessels that can handle a wide variety of cargoes. A few may build a vessel for a particular user on a particular multiyear contract.

Many configurations of vessels exist based on intended purpose and on a variety of designs. For example, certain vessels intended to be used for international trade into the Great Lakes will be designed to lift maximum tonnages of cargo on the draft and beam constraints imposed by the Saint Lawrence Seaway. The seaway restrictions are currently about 7.925 m (26 ft) freshwater draft, 23.8 m (78.1 ft) beam, and about 225 m (738 ft) length overall.

* Major bulks totaled 448 Mt in 1970, 796 Mt in 1980, and 968 Mt in 1990.

† Totals may reflect rounding errors.

(LOA), but the last is usually not a serious restriction—the beam and draft are the most serious.

The vessel description is crucial for all personnel involved in vessel chartering. Fundamentally, the vessel must fit into its intended load and discharge ports and berths; its configuration will also influence how much cargo can be carried and how fast it can be loaded and unloaded.

The vessel description can have legal implications as well, when the vessel is described in the *charter party* between the vessel owner and the charterer. The charterer must exercise extreme diligence to be certain that vessels are capable of meeting the requirements of sales contracts on the underlying commodities.

Numerous vessel designs exist within the bulk carrier category. Four common designs are encountered in the industrial minerals trades: *TESS45* type, *Federal Oshima* type, *Federal Shimanto* type, and *Federal Saint Laurent* type.

The *TESS45* vessels (and their larger and smaller similar designs), as well as similar type vessels, are workhorses trading all over the world. These vessels, many of which are controlled by the Montreal-based shipowner Fednav Ltd., are worth noting because their design configuration allows them to trade into and out of the Great Lakes, and they are able to maximize the cargo intake on the draft and maximum beam restrictions of the Lakes–Seaway System. A number of shipowners and vessels can and do trade into and out of the Great Lakes—where the typical season runs from April through the middle of December. After about December 15–25, the system is closed for the winter; any ships that are late in exiting are sometimes caught until the system reopens at the end of March of the following year.

Numerous minerals parcels are imported through the Great Lakes, most coming from the Far East, Australia, New Zealand, Africa, and South America.

Shoreside Facilities: Terminals and Equipment

Depending on the commercial terms of the commodity sale, the cargo interest may become involved with the loading and discharging of the cargo. There are many terminals and facilities where industrial minerals can be loaded and unloaded, but the terminals are links in a broader supply chain.

The choice of a terminal for use in a particular cargo move will depend on a host of factors, some of which, in turn, will depend on capabilities or requirements in a particular commercial contract. Although there are some exceptions (for instance, in a dedicated run over an extended period of time), the charterer must warrant to the shipowner that the port is a safe port. Shippers (and receivers) of minerals should require a similar warranty from their business partners in the supply chain who are actually responsible for nominating the particular port.

Some of the important factors to be considered in choosing an actual berth for cargo operations are the following:

- Draft: What is the depth of water alongside the loading or discharging berth?
- Airdraft: What is the height above the waterline of the highest point on a vessel?
- Storage: Can cargo be stored without contamination or exposure to elements?

Table 3. The dry-bulk shipping fleet

Year (start)	Existing Fleet	Subtract: Layup	Tons Operating	Add: Combination in Dry	Operating Dry Fleet*

Adapted from *The Platou Report 2004*; Clarksons Research Services Limited 2005.

* The end-2004 fleet of Handysize bulk carriers in the 10,000–40,000-dwt (deadweight ton) range comprised 2,742 vessels. The average vessel deadweight within the category was approximately 26,600 dwt. Within the Handysize fleet, 57% of the tonnage was 20 years old or older, and 25% was less than 10 years of age. At the end of 2004, approximately 66.8 Mdwts of dry-bulk tonnage was on order, including 161 vessels comprising 4.7 Mdwts in the Handysize sector. Size breakdown may reflect rounding practices and discrepancies between sources.

- Rail access: If the cargo comes inbound by rail (or is forwarded on to a receiver with a rail facility), does the terminal have rail access?
- Barge access: If the cargo comes inbound via the river system (or is trans-shipped into a barge after arrival at a port), is the terminal situated so that barges can load or unload alongside the vessel or at adjacent berths? Are barges available?
- Truck access: For very small lot sizes, or where minerals are shipped in containers, can trucks easily service the terminal?

- Handling equipment: Is the type of equipment suitable for the cargo being shipped? Are gantries (on shore) or floating equipment (in the river) suitable for handling of the cargo? What rate of throughput is provided? Is the rate of throughput consistent with underlying commercial terms?
- Physical restrictions: Do the vessel dimensions interfere with quick loading and discharging of the cargo at the particular terminal? Can the cranes (shore cranes or loading equipment) reach into the holds of the ship?
- Waterside: Is the dock long enough to accommodate a particular vessel?
- Hours: Does the terminal support the 24-hour work usually needed for minerals movements?
- Dimensions: Is the water deep enough at the dock, even at low tide, to accommodate the vessel? At high tides, will the vessel dimensions enable it to remain clear of any obstructions?
- Restrictions: Clarify in advance that the terminal will allow normal vessel operations, which may include taking on fuel (by barge), delivery of supplies, or crew changes.
- Regulatory: Confirm that the terminal is in compliance with regulations relating to environmental or maritime security matters.

MARKETING: THE MAJOR TRADES AND THE BROKER NETWORK

The demand for ocean freight represents derived demand, reflecting patterns in the materials markets that underpin the demand for freight. As noted in the Statistics subsection in this chapter, the marketplace for freighting of industrial minerals is a subset of the much broader dry-bulk transportation market.

Shipowners and cargo interests are located all over the world and are often represented by shipping brokers who are compensated by commissions that represent a small portion of the gross freight. The shipowner pays the commission. Shipbrokers are on call 24 hours per day, 7 days per week, throughout the year. *SHINC* means “Sundays and holidays included,” and, because of the global nature of the shipping market and the fact that there may be hundreds of relationships (if not thousands) that need to be managed continuously, SHINC is especially important during periods of high volatility. It is important that the “right” broker be used to suit the individual client’s needs and market coverage. Historically, shipping brokers add value by filtering the enormous amount of market information generated daily and enabling charterers to minimize their freighting costs, subject, of course, to achieving optimal transportation coverage for their raw materials movement program.

In today’s globalized economy, and because of the interconnectivity of the relationship of ocean freight to the other demands of the total supply chain, the broker must understand all facets of the shipment in question. Even in today’s high-technology environment, the broker is more valuable than ever in interpreting market conditions and developments while guiding their client. Brokers are bound by their commitment to integrity and professionalism. Thus, “choose your broker carefully and wisely” is sound advice.

The role of the shipping broker is paramount in arranging transportation of industrial minerals. Historically, brokers have specialized in representing either shipowners or representing charterers of ships; with the vast improvements in communications throughout the 1990s and 2000s, however, the lines have become increasingly blurred. Typically, brokers in London, Oslo, Greece, and Hong Kong have specialized in representing owners. The charterers’ brokers have clustered in business centers tied to the processing of raw materials. Singapore has emerged as a shipping center, particularly

after reversion of control of Hong Kong to the People's Republic of China in 1997. With the ascendancy of Asian economies, Singapore, Seoul, and now Beijing continue to grow in importance.

The Role of Barging in Logistics

The movements of industrial minerals are often part of supply chains encompassing numerous intermediaries and multiple transportation modes. The imported raw materials may not be processed at or near an actual port of importation but rather at a facility on the U.S. inland waterway system (Figure 1).

More than 1 billion st of materials annually move throughout the inland waterway system, as shown in Table 5.

Table 6 shows the breakdown of movements on the inland waterway system by commodity groups and by river systems. Industrial minerals fall within the crude minerals group. As in the deep-sea shipping segment, minerals comprise a very small percentage of the overall totals. Geographically, most of the trade originates on the Mississippi River and the Ohio River branches.

Mineral cargoes transported on the inland waterway system will typically move in covered barges. A towing company will put together a tow consisting of up to 30 barges of various types. The typical covered barge, with a rake shape, has the following dimensions.

Length:	59.44 m (195 ft) to 60.96 m (200 ft)
Beam:	10.67 m (35 ft)
Depth:	2.74 m (9 ft)
Light draft:	0.53 m (1 ft 8 in.)
Cargo:	
On 2.74-m (9-ft) draft	1,360 t
On 3.0-m (10-ft) draft	1,542 t

The 1,360-t cargo capacity of the typical barge compares with the 91-t capacity of a railcar and the 22.7-t size of a cargo truck, enabling greater economies of scale for barge transport over the other transport modes. In evaluating the economics of moving cargo originating at, or destined for, locations not directly contiguous to a navigable waterway, the cost of additional rail or truck transport must be considered.

The overall barge fleet (Table 7) has some 24,530 dry-cargo barges that trade on the Mississippi River system and inland waterways. The dimensions of the barges have been standardized to enable them to meet physical restrictions on the river system, including locks on the Upper Mississippi and tributaries, as well as draft restrictions.

As with deep-sea shipping, bulk commodities moving in barges are not subject to rate regulation, but the barges and towsboats must comply with safety and security regulations promulgated by the U.S. Coast Guard.

Economics

Freight Rates Over Time

The interaction of vessel supply and demand leads to the *time-charter* hire rates (dollars per day) and voyage freight rates (dollars per ton), which are described in this section.

The rates that are paid by shippers of industrial minerals are quoted on voyage terms, in dollars per ton (in worldwide trade, this is generally *per t*). The rates on a given move will depend on many voyage-specific criteria but also on the general levels of the freight market as determined by the supply and demand interaction. These rates reflect conditions for many vessel types capable of hauling dozens of different materials throughout the world.

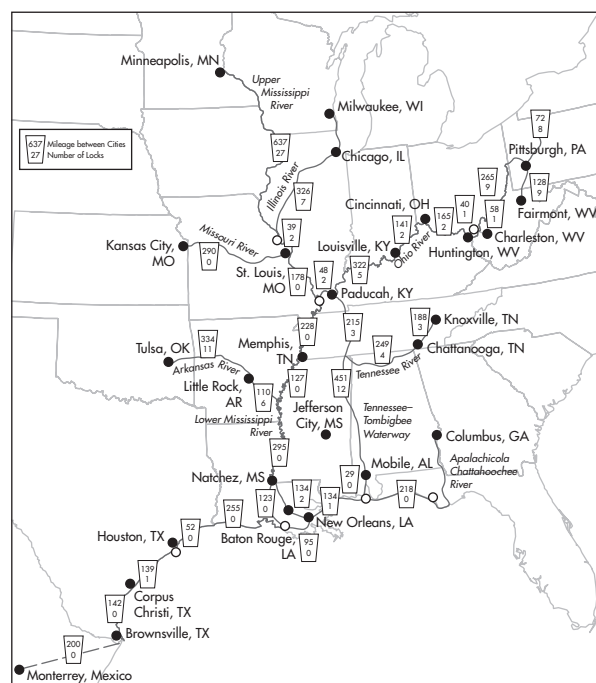

Figure 1. Map of the U.S. inland waterway system

The general market levels are indicated by timecharter rates, which reflect what the charterer will pay, on a dollars-per-day basis, for the use of a vessel. Under the timecharter contract the shipowner must maintain the vessel and supply the crew. These timecharter rates (sometimes called “hire” rates) are converted by the shipowner into the more familiar dollars-per-ton rates quoted to minerals shippers.

Figure 2 shows the trend in hire rates from the mid-1970s through 2003 for two types of Handysize vessels (16,000 and 30,000 dwt). These rates represent period timecharter employment, meaning that they are not sensitive to geography. Six time series are shown; each of the two vessel types has three time series: 6-month charters, 1-year charters, and 3-year charters. The graph shows the 6-month rates to be more volatile than the longer-term rates across both size categories. The market’s upward spike in 2003 is visible on the right side of the graph.

Figure 3 shows daily hire rates for selected Handymax timecharter routes for vessels of approximately 45,000 dwt, including the TESS45 types, from mid-2000 through mid-2004. Unlike the period timecharter rates in Figure 2, these hire rates are sensitive to geography. The rates for trips from the Atlantic Ocean to the Pacific Ocean (U.S. Gulf–Far East and trip out to Far East) are higher than those for trips where vessels remain in the Pacific. As in Figure 2, the market’s sharp upturn in mid-2003, where vessels such as the TESS45 types could earn as much as \$50,000/day, is clearly visible across each of the time series.

Timecharter to Voyage Conversions

Freight rates in the bulk trades are freely negotiated between the charterer and the shipowner or operator. Shipowners base freight rates on prevailing market levels, as reflected in terms of dollars-per-day timecharters. In their conversions, shipowners begin with a timecharter rate that would reflect the prevailing market conditions at the time of the negotiation. The calculations start with a dollars-

Figure 2. Timecharter rates for Handysize vessels (1976–2004), kdw

per-day timecharter value for the vessel, then build in other costs of the voyage (fuel, port-related, and sometimes canal costs) based on the estimated number of days in the voyage, which is then divided by the number of tons carried to arrive at the cost per ton. Depending on the relative negotiating strengths of the owner versus the charterer, the actual voyage rate agreed-on may work back to a timecharter return to the owners that is above (or below) the prevailing levels.

The overriding factor in determining the final freight level paid will be market demand at the time of negotiation. The shipowner will do their calculation, evaluate the market, and determine the desired return, but the minute there is competition (be it between different shipowners or different charterers), all the calculations will become moot and the freight rate will be established according to final negotiations and who wants the business more.

Figure 3. Timecharter rates for Handymax trades

The shipowners are quite adept at evaluating different financial results from the thousands of messages received daily advising them of cargo inquiries, port congestion, costs, etc. A good broker representing the charterer becomes invaluable, with the capability to level the playing field and, in most cases, bring competing shipowners to the negotiating table. In some cases, all that may be necessary for the charterer to benefit is for the broker to somehow convincingly create the perception of competition.

The voyage rates in charter calculations are predicated on free in and out (FIO) terms to the shipowner. The cargo shipper or receiver rather than the shipowner will pay for loading and discharging. The dollars-per-ton cost for loading and discharging the cargo will be negotiated separately between the shipper or receiver and the terminals at each end.

Shipowners and cargo shippers have developed standardized ways of estimating the profitability of voyages, based on conversions between the shipowners' timecharter dollars-per-day (timecharter) rates and the cargo shippers' focus on dollars-per-ton (voyage) rates. The calculations will yield unique results for each set of parameters entered regarding the vessel, load and discharge rates, fuel prices, voyage routing, and other factors. These calculations are done on proprietary software.

The actual agreed-on rate will be the result of negotiations between owner and charterer. The shipowner will use computerized calculations run internally and in conjunction with a broker to develop a freight quote. The cargo shipper may use similar analytic tools to estimate the likely economic return that the shipowner is earning, and may use such an analysis in negotiations. Calculations of a freight quote contain estimates such as port costs and fuel consumption as well as miscellaneous costs and extra days to account for weather-related contingencies. Each participant may estimate the voyage costs somewhat differently. In any case, efficient operation is rewarded. If a number of participants are using a particular cost or a standard number of days for a particular activity, that time interval will be reflected in the prevailing dollars-per-ton rates negotiated in the marketplace. If a certain shipowner can perform the activity more cheaply than others, or in a shorter time period, the timecharter (dollars-per-day) equivalent of the dollars-per-ton rate will be enhanced. Note that market conditions that vary weekly, daily, and sometimes hourly determine the ultimate freight rate.

REGULATION

Shipping is an international business, and therefore the regulatory system is international. This section has no discussion of economic regulations such as freight tariffs because the bulk shipping business is economically unregulated.

Most of the regulations governing the safe operation of vessels, the handling of cargo, and the newly important maritime security concerns are coordinated through the auspices of the International Maritime Organization (IMO), a United Nations body based in London. Member countries where vessels are registered and documented are known as Flag States. Flag States enact legislation that implements provisions agreed on in IMO conventions. For example, in the United States, the U.S. Coast Guard promulgated regulations in 2003 that reflected an IMO agreement reached in late 2002. Nations that interface with vessels through cargo loading or discharging operations are called *Port States*, and those vessels may transit the economic zones of coastal states. Table 8 shows leading Flag States as of March 1, 2004. Note that the leading industrial countries, which generate trade, are not the leading Flag States.

IMO membership comprises 160 countries that negotiate and agree on international diplomatic conventions. The ratification procedure gives leading Flag States a greater weighting. The dictates of Flag States are very often delegated to classification societies that examine vessels. As an example, the U.S. Coast Guard performs vessel inspections but also delegates parts of this role to the American Bureau of Shipping, one of the world's leading classification societies.

Some of the more important regulatory conventions, negotiated at the IMO and enforced by flag, port, and coastal states, are as follows:

- SOLAS (Safety of Life at Sea), an international agreement that covers the safe operation of vessels, and also tonnage measurement and certain cargo-stowing practices aboard vessels.
- MARPOL (Maritime Pollution Convention, also known as the International Convention for the Prevention of Pollution of Ships) that covers oil or other pollution matters and compensation for pollution incidents.

Table 8. Leading shipping registries (Flag States)

Flag State	Number of Vessels	Vessels, dwt	Combined Number of Vessels	Combined, dwt	Number of Bulk/Ore Vessels	Bulk/Ore, dwt	Total Number of Vessels	Total, dwt	Percentage

- ISM (International Ship Management) Code that covers shipping company management practices onshore and onboard vessels.
- ISPS (International Ship and Port Security) Code that covers security matters at port facilities, within shipping companies, and aboard vessels.

This is only a partial list; there are approximately 40 international conventions on matters related to maritime trade and shipping. Issues of cargo carriage are considered in both the SOLAS and MARPOL rules as well as the International Maritime Dangerous Goods (IMDG) Code, originally a supplement to the SOLAS rules, which became mandatory on January 1, 2004.

Disputes between shipowners and charterers of the vessels are generally settled by panels of arbitrators following well-established sets of precedents and industry practices. The brokers in most major shipping centers are members of industry associations that unofficially enforce standards of acceptable business conduct in the absence of formal regulation. Arbitration panels are usually convened in either London or New York. Very rarely, when one party is not satisfied after having exhausted the arbitration route, it will bring suit through the court system. Longer-term contracts may stipulate that the initial recourse will be through the courts.

OUTLOOK AND FUTURE TRENDS

The bulk freight markets represent a pure economic marketplace. Rates are determined by the interaction of supply and demand with vessel charters negotiated through the broker network. The industry has been subject to dramatic increases in regulatory scrutiny in recent years concentrating on safety and then on security. Following the advent of the ISPS Code in 2004, no economic regulation exists in bulk shipping.

In the summer of 2003, freight levels across the range of vessel sizes moved sharply higher, peaking in the late winter of 2004 before dropping slightly. After a softening of 2 months' duration, rates moved sharply upward again throughout 2004, in many cases eclipsing the highs set earlier in the year. In the late winter and into the spring of 2005, the market softened, albeit to levels that were very firm by historical standards.

The market strength can be attributed to demand stemming from dramatic increases in the demand for raw materials in China and other Asian countries, especially in the iron and coal trades. Not only were cargo tonnages up substantially, but longer hauls were also the norm. Incremental iron ore demand was sourced from

Brazil rather than from Australia, the conventional source. The existing fleet could deliver fewer cargoes each year because the haul from Brazil was farther, thereby putting extreme upward pressure on the available supply of vessels. The raw material movements first affected the Cape size sector, with the tightness spreading to the Panamax and Handymax sectors as well. As China's steel production increased, exports of finished products brought about a surge in demand for Handymax tonnage.

As has been the case historically, expectations of future levels brightened in the stronger market, leading to a surge in orders for vessels, with deliveries scheduled for 2005 and into 2006. Analysts are evaluating how the interaction of volatile demand with increasing supply would play out. In early 2005, spot market rates were much higher than forward rates as evidenced by period time charters where vessels are taken for 1, 2, or even 3 years, or by increased activity in the nascent forward-freight market, a sector where financial contracts tied to freight indices are traded. The forward discount suggested that most market participants felt that the market would soften.

From the 1980s through 2003, certain ceilings on rates were in evidence. The market surge of 2003 broke through those ceilings. Generally, demand can be very volatile as charterers flood the markets with cargoes and then pull back if rates appear to be moving sharply upward.

According to technical analysts who focus on the patterns of rates, when rates do retrench, they settle at levels above the previous highs. The psychology of the freight markets is no different than other commodity markets, where traders "buy on the dips," having missed a chance to buy earlier. In Figure 3, showing freight rates for Handymax vessels, the previous ceiling was in the region of \$10,000/day. Although it is impossible to provide a precise forecast, a likely pattern for the future is that freight rates will be very volatile, at levels above the market highs of pre-2003. The freight levels will be set through continual testing of previous lows (and highs, when the market surges upward).

Fundamental forecasters, who look at the size of the fleet in relation to demand, point to an increased supply of new vessels as they are delivered from shipyards. Most analysts, however, expect strong demand from China, India, and other Asian economies, which may continue to fuel the market and absorb at least the initial new tonnage.

A shipbroker with expertise in the movements of industrial minerals does far more than merely "fix" ships. The broker can

advise opportune times to charter vessels, in addition to providing clients with a complete picture across the many different trades that comprise the charter market.

GLOSSARY

All details about: All details about.

Bareboat charter: A contractual arrangement in which a vessel owner pays finance costs only, but then charters the vessel out to a bareboat charterer that will be responsible for the actual operation (crewing, maintenance, insurance) of the vessel. The bareboat charterer will then act as an owner with respect to freight transactions in the marketplace.

Barge: Nonself-propelled vessel generally used for transportation in a river and inland waterway system.

Beam: The width of a vessel.

Bill of lading: Document evidencing ownership of the cargo, issued by the vessel's master. The bill of lading weight indicates how much cargo has been loaded aboard the vessel.

Bulk carrier: A vessel dedicated to the transport of solid bulk cargoes.

Bulk shipping: Shipping of materials that are not packaged. Generally refers to industrial raw materials (e.g., coal, iron ore) and agricultural commodities.

Capesize: A vessel that is unable to transit the Panama Canal because of its size. Generally refers to dry-cargo vessels greater than 80,000 dwt and are typically in the size range of 130,000 to 180,000 dwt. Such vessels typically transport iron and coal.

Charter party: The contract between the charterer and the owner (or controlling party) of a vessel that outlines the terms and conditions of carriage. The terms of the contract will vary depending on the trade and market circumstances. Broadly, the charter party will cover voyage freighting or a timecharter of the vessel.

Charterer: The buyer, or user, of freight services. May also be the actual shipper or receiver of the cargo, but may also be an intermediary that, in turn, subcharters the vessel onward or provides parcel transportation.

Class: The major classification societies are Lloyds Register (LR), American Bureau of Shipping (ABS), Det Norske Veritas (DNV), Germanischer Lloyd (GL), and Bureau Veritas (BV). See also Classification society.

Classification society: An inspection company, usually with surveyors stationed in ports around the world, that supervises technical inspections of vessels, often acting in the capacity as the inspection arm of Flag States.

Contract of Affreightment: A timecharter agreement calling for multiple liftings of either full vessel loads, or parcels, usually between the same loadport (or range of ports) and discharge port (or range of ports).

COP/CQD: Custom of the port/customary quick dispatch. These terms, typically used together and in place of fixed loading and discharging speeds, remove a good amount of risk and exposure to the cargo interests, and, conversely, place a greater risk and more exposure on the shipowner.

Deadweight tons (dwt): The carrying capacity of a ship measured in terms of the weight, in tons, of the cargo, fuel, provisions, and passengers that the vessel can carry.

Deep-sea vessel: Vessels that trade between ports on voyages that take the vessels more than 80 km from shore. Generally, this designation refers to manned vessels of at least 500 gross tons that are subject to the SOLAS Convention.

Disponent owner: The owner, in a contractual sense, of a vessel that is chartered in from the actual owner (or another disponent owner).

Draft (or draught): How deep a vessel is submerged below the waterline.

DWAT: Deadweight all told. The total deadweight, including cargo, fuel provisions, etc.

FFA: Forward freight agreement—a contract with a financial settlement, between a buyer and seller of forward freight, tied to levels of a freight index or one or more routes with a freight index, used for hedging purposes.

FIO: Free in and out, from the vessel's viewpoint. The cargo interest(s), who may be the charterer of the vessel (or may be the shipper or receiver), must arrange and pay for loading and discharging of the cargo.

FIOST: Free in and out, stowed and trimmed—where the charterer is also responsible for the stowing of the cargo (typically break-bulk/general cargo), or, in the case of bulk commodities, where the charterer is also responsible for the trimming of the cargo.

Fixing or fixed: The process of freight negotiations that will lead to a binding contract between the shipowner (carrier) and the charterer—that is, “we are now fixed.”

Flag State: The country where a vessel is registered, responsible for enforcement of international safety and technical regulations.

GR/BA: Grain/bale—the cubic capacity of the vessel’s cargo hold, measured in either cubic meters or cubic feet. Grain capacities—measuring capacity for freely flowing cargo—will usually exceed the bale measurement, which refers to baled cargo.

GRT: Gross register tons—a volumetric measurement (each ton = 100 ft³) used to describe a vessel, especially for computing wharfage and port costs.

GRT/NRT: Gross register tons/net register tons—in vessel descriptions, both are used, with the NRT measure referring to the volume in cargo spaces.

Handysize, Handymax, and Super Handymax: Handysize vessels are usually 15,000–35,000 dwt, Handymax vessels are typically 37,000–48,000 dwt, and Super Handymax vessels are 50,000–55,000 dwt. They take a wide range of bulk cargoes, with Handysize, and lately, more Handymax-size vessels, being frequently employed in the parcel trades.

HO/HA: Holds/hatches—the number of cargo holds and the number of hatches, in ship descriptions.

Lakes draft: Allowable draft for vessels transiting the Saint Lawrence Seaway, connecting the Great Lakes with the Saint Lawrence River.

Liner service: A shipping service according to fixed schedules known and widely published in advance. Contrasts with *tramp service*.

Liner terms: A charter contract where the shipowner, or carrier, is responsible for the loading and discharging of the cargo. Contrasts with *FIO* terms.

LOA: Length overall (of a vessel).

Long ton (lt): A unit of weight equal to 2,240 lb.

Metric ton (t): A unit of weight equal to 1,000 kg (typically converted as 2,204.6 lb).

Operator: In the bulk shipping context, a seller of freight services on vessels that are chartered from the actual vessel owner (or from a disponent owner).

Owner: The seller of freight services. May also be the carrier that deals with the charterers, but not in cases where the owner is acting as an intermediary (chartering the vessel outward to another owner who may actually be dealing with cargo owners). Generally the *head* or *registered* owner is the financial and legal owner (and ultimate controlling party) of the vessel.

Panamax: Refers to the largest vessels that can transit the Panama Canal, effectively limited by the maximum breadth (beam) of 32.26 m (just shy of 106 ft). Based on current vessel design criteria, such restrictions typically equate to vessel deadweight

sizes ranging from about 60,000 dwt (usually older vessels) up to a maximum of about 78,000 t (newer vessels). Such vessels carry a wide range of bulk cargoes, including grains, coal, and iron ore. They may also transport industrial minerals parcels.

Parcel shipment: A shipment less than the full carrying capacity of a vessel. Typically, multiple parcels will be handled by shipowners and operators who typically specialize in providing such parcel service.

SHEX: Sundays and holidays excluded—referring to time allowed for vessel loading and discharging.

SHINC: Sundays and holidays included—referring to time allowed for vessel loading and discharging.

Short ton (st): A unit of weight equal to 2,000 lb.

SOLAS Convention: Safety of Life at Sea Convention—the body of international law that governs the safe operation of vessels.

Spot charter: A charter for one lifting, typically loading within several days of concluding the charter (or fixture), as distinguished from a consecutive voyage charter, or a lifting done under a contract for multiple liftings. Usually refers to a voyage arrangement where the charterer pays an agreed-on dollars-per-ton freight rate under voyage terms.

SSW: Summer salt water—the DWAT of a vessel can vary depending on the salinity of the water, and SSW specifies that the deadweight described is measured using salt water, without any restrictions for winter conditions.

Stowage factor: The number of cubic feet per ton that a specific commodity will occupy in the vessel’s holds. Industrial minerals are typically dense cargoes with stowage factors in the range of about 15 to 40 ft³/t (as well as lower and higher).

Timecharter: A charter contract in which the charterer pays a daily hire rate (dollars per day) for the use of the vessels. The charterer directs the movement of the vessel and must pay fuel, port, and canal costs.

TPC: Tons per centimeter immersion—the number of tons of cargo that will cause the vessel to draw an additional centimeter of draft.

Tramp service: A trading pattern in which the vessel is not on a fixed schedule, instead booking “cargoes of opportunity,” that is, at each time of availability and after evaluating the potential profitability as well as projected ongoing employment. This type of service contrasts with *liner service*.

Trimming: Refers to the arranging of bulk material in the vessel hold for optimum stowage and vessel stability characteristics, and to minimize the possibility of cargo shifting (as may happen with some commodities).

Voyage charter: A charter contract where a freight rate is quoted on a dollars-per-ton basis. The owner of the vessel operates the vessel but also must pay for fuel and port costs.

Mine Safety and Health Law

Anne T. Nichting, Laura E. Beverage, and Karen L. Johnston

Federal regulation of workplace health and safety in the mining industry has developed as a consequence of growing national concern over recurring fatal accidents and mining disasters. Today, safety and health in the mining industry is governed by the Federal Mine Safety and Health Act of 1977 (known as the Mine Act). When Congress passed this legislation, it stated, “The first priority and concern of all in the coal or other mining industry must be the health and safety of its most precious resource—the miner” (Mine Act, Section 2[a]). (The Federal Mine Safety and Health Act of 1977 is codified at 30 U.S.C. Section 801, *et. seq.* For ease of reference, however, all subsequent citations to the 1977 Mine Act in this chapter will refer to the specific section of the Mine Act and not the U.S.C. citation.)

The Mine Act is extremely complex with a variety of exceptions and details that are beyond the scope of this chapter. Compliance with the Mine Act, and the regulations adopted pursuant to it, depends on the specific facts and circumstances of a given situation. Therefore, nothing in this chapter should be considered as the rendering of legal advice, and readers are responsible for obtaining legal advice from their legal counsel with respect to any specific situation. The information provided is intended for educational purposes only.

HISTORY AND KEY COMPONENTS OF THE MINE ACT

Mining has a long history in this country, as does the federal government’s efforts to regulate what has been perceived to be a dangerous occupation and workplace. Regulation of the health and safety of miners in the United States began in 1891 with the first federal statute governing mine safety, “An Act for the Protection of the Lives of Miners in the Territories,” Chapter 564, 26 Stat. 1104 (1891) (known as “the 1891 Act”).

This legislation, which applied only to mines in the U.S. territories, established several mandatory safety standards, including minimum ventilation requirements at underground coal mines, the construction of escape shafts, the use of safety catches, and hoisting equipment requirements, and prohibited operators from employing children less than 12 years of age. The 1891 Act authorized the U.S. president to appoint mine inspectors for each U.S. territory. The inspectors were required to check the mines in their territories annually and provide reports to the U.S. secretary of the interior.

It was not until 1952 that Congress passed the first federal statute granting inspectors the authority to cite an operator for violation of a federal safety standard. The Federal Coal Mine Safety

Act Amendments of 1952, Public Law 82-552, 66 Stat. 692 (1952) (known as “the 1952 Act”) was designed to supplement, but not replace, existing state regulations. Applied to all coal mines with more than 14 miners, the 1952 Act set forth mandatory safety standards, established enforcement procedures and review, and mandated annual inspections in certain underground coal mines. However, the penalties authorized by the 1952 Act were minimal and could only be assessed for entering an area closed by a withdrawal order or for refusing to admit an inspector onto mine property. Failure to comply with the mandatory safety standards would not result in a penalty against the operator. The 1952 Act gave inspectors the authority to issue withdrawal orders for (1) situations of imminent danger or (2) where the operator had failed to abate a violation within the stated amount of time. These two types of withdrawal orders remain part of the enforcement scheme today.

In 1966 Congress passed legislation specific to non-coal mines. The Federal Metal and Nonmetallic Mine Safety Act of 1966, Public Law 89-577, 80 Stat. 772 (1966) (known as “the 1966 Metal/Nonmetal Act”) provided for minimal enforcement authority in the nation’s metal and nonmetal mines. The 1966 Metal/Nonmetal Act differed somewhat from existing coal mine legislation in that it promulgated standards, many of which were advisory and not mandatory.

In 1969, Congress passed the Federal Coal Mine Health and Safety Act, Public Law 91-173, 83 Stat. 742 (1969) (known as “the 1969 Coal Act”), which was more comprehensive and stringent than any previous federal legislation governing mine safety. The 1969 Coal Act covered surface and underground coal mines, required two annual inspections of surface operations and four annual inspections of underground operations, and greatly increased federal enforcement powers. Violations of the 1969 Coal Act would result in monetary penalties, and criminal penalties could be imposed for knowing and willful violations. With the 1969 Coal Act, Congress expanded upon and strengthened previously existing safety standards and adopted health standards. The 1969 Coal Act included specific procedures for the development of improved mandatory health and safety standards and provided compensation for miners who were totally and permanently disabled by “black lung” disease.

The legacy of the foregoing safety and health legislation, however, was its ineffectiveness at making the mining industry safer, resulting in passage of the 1977 Mine Act. Basically an enforcement act, it was borne out of congressional frustration with multiple

mine disasters seen as a result of operators' indifference to safety and health. The mine disasters included a 1968 explosion at a coal mine in Farmington, West Virginia, that left 78 miners dead; a 1972 fire at the Sunshine silver mine in Kellogg, Idaho, that claimed the lives of 91 miners; and two explosions in 1976 at the Scotia coal mine near Whitesburg, Kentucky, that left 26 dead.

Congress noted:

The [1976] Scotia disasters demonstrated once again that until Congress finally provides truly effective mine health and safety laws, and insists on responsive administration and enforcement of those laws, this problem will continue to occur. (Senate Committee on Human Resources, Federal Mine Safety and Health Amendments Act of 1977, S. Rep. 95-181, 4-5 [1977])

The Mine Act repealed the 1966 Metal/Nonmetal Act and amended the 1969 Coal Act to make it applicable to all types of mines. Under the Mine Act, many functions and duties that were the responsibility of the secretary of interior under the Coal Act were transferred to the secretary of labor. The Mine Act provides the statutory framework for the Mine Safety and Health Administration's (MSHA's) enforcement authority and sets forth a number of enforcement tools. Some of the major features of the Mine Act are the following:

- Transferred the federal agency charged with enforcement of federal mine safety and health legislation from the Department of the Interior to the Department of Labor (MSHA) on March 9, 1978
- Strengthened the enforcement tools that were available to the government
- Increased emphasis on protecting miners' health
- Allowed for greater involvement of miners or their representatives in processes affecting their health and safety
- Set up procedures for assessing and collecting civil penalties resulting from violations of regulations
- Provided broad mandatory training requirements for miners

FEDERAL MINE SAFETY AND HEALTH REVIEW COMMISSION

The Federal Mine Safety and Health Review Commission (the "Review Commission") was created by the Mine Act to provide for an impartial tribunal to hear contested cases. The Review Commission and its Administrative Law Judges (ALJs), assigned to the Department of Labor, are responsible for reviewing the lawfulness of the labor secretary's enforcement actions. In addition, the Mine Act grants the Review Commission broad authority to formulate national policy pursuant to the Mine Act, issue declaratory orders to ensure compliance with the Mine Act, and consider constitutional questions.

Created by Congress in 1977, the Review Commission is a five-member panel patterned after the Occupational Safety and Health Review Commission. The president, with the advice and consent of the Senate, appoints the commissioners for 6-year terms. The Mine Act requires that commissioners possess the training, education, or experience necessary to carry out the functions of the Review Commission.

Review Commission ALJs have jurisdiction to review: (1) citations and withdrawal orders, (2) the reasonableness of abatement times, and (3) the modification or termination of citations and orders. In addition to hearing enforcement actions, the ALJs hold hearings on Section 105(c) discrimination complaints and Section

111 compensation claims. ALJs are career government officials with lifetime appointments.

Strict Liability

The Mine Act states that the secretary of labor *shall* issue a citation whenever the secretary believes that a mine operator has violated its requirements or any of its mandatory standards (Mine Act, Section 104[a]). In addition, the Mine Act requires that a penalty be assessed against "[t]he operator of a...mine in which a violation occurs" (Mine Act, Section 110[a]). The courts have interpreted these two provisions of the Mine Act to hold that a mine operator is liable for a violation of the act or its regulations, even if the operator did not cause or create the violation. This principle of liability without fault for violations of the Mine Act and its regulations means that an operator can be held responsible for violations committed by either hourly or salaried employees and, under certain circumstances, for violations committed by independent contractors.

Enforcement Provisions and Penalties

Under the Mine Act, MSHA has at its disposal a number of enforcement tools, commonly referred to as *citations* and *withdrawal orders*. As discussed in more detail later, a citation requires corrective action to be taken but does not result in cessation of the activity or equipment at issue. In contrast, a withdrawal order results in halting the activity or the use of a piece of equipment subject to the order. The MSHA inspector has a fair amount of discretion in deciding which type of enforcement action to issue. However, the enforcement action must meet the legal standards, which have been further refined by case law, in order to properly classify a violation under each provision of the Mine Act. In addition, a key issue under the Mine Act's enforcement section is MSHA's determination of special findings, which are discussed in more detail in the Special Findings section of this chapter.

Citations

The most commonly issued enforcement action is Section 104(a) of the Mine Act. If, as a result of an inspection or investigation, an inspector believes that an operator has committed a violation of the Mine Act or any of its implementing rules, regulations, or orders, the inspector must issue a citation to the operator with "reasonable promptness" (Mine Act, Section 104[a]). The citation must describe the particular nature of the violation and must allow a reasonable abatement period.

The description of the violation usually consists of a summary of the condition or practice the inspector believes to be in violation of the standard and the identification of the specific area or piece of equipment involved. The citation must also indicate the MSHA standard or section of the Mine Act that the inspector alleges was violated. The MSHA inspector also notes the date by which the violation must be corrected or abated. Failure to comply may result in a withdrawal order for failure to abate.

Withdrawal Orders

An MSHA inspector may issue a variety of withdrawal orders, depending on the circumstances. The effect of a withdrawal order is to immediately shut down the area, equipment, or practice that is alleged to be in violation of the standards. All personnel associated with the condition or practice must be withdrawn, except those necessary to correct the violation.

Imminent Danger. Under Section 107(a), MSHA can issue a withdrawal order for a condition or practice "which could reasonably be expected to cause death or serious physical harm before such condition or practice can be abated," regardless of whether

the condition or practice violates a standard or rule (Mine Act, Section 3[j], 107[a]). A federal appellate court decision interpreted the Mine Act's imminent danger language to mean that a Section 107(a) order is appropriate when the condition or practice observed could reasonably be expected to cause death or serious physical harm to a miner "if normal mining operations were permitted to proceed in the area before the dangerous condition is eliminated" (*Eastern Associated Coal Corp. v. Interior Board of Mine Operations Appeals*, 491 F.2d 277, 278 [4th Cir. 1974]). A violation of Section 107(a) does not require a finding of violation of a mandatory safety or health standard. However, the imminent danger finding may be coupled with such a finding and result in increased penalty amounts. If a MSHA inspector believes that a condition or practice presents an imminent danger, the inspector must determine the area affected and immediately direct the withdrawal of all persons, except those necessary to abate the condition or practice.

Failure to Abate. A withdrawal order may be issued for the area or equipment affected by the violation for a failure to abate, or correct, the violation within the time prescribed (Mine Act, Section 104[b]). Failure-to-abate orders can result in penalties of up to \$6,500 per day that the condition continues.

As discussed, a MSHA inspector is required to establish a reasonable time for abatement of the conditions cited. On reinspection, the inspector determines whether the citation has been corrected and, if not, whether the circumstances warrant an extension of the abatement period. If no extension is warranted, the inspector will issue a Section 104(b) withdrawal order requiring all persons in the area affected by the violation to leave immediately. A failure-to-abate closure order prohibits all persons from entering an area covered by the order, except those necessary to correct the violation. Once the inspector determines that the violation is fully corrected, the closure order is terminated.

Untrained Miner. Under Section 104(g), a withdrawal order will be issued for failure to provide mandatory training required under the Mine Act. When a Section 104(g) order is issued, it will identify the specific miner(s) lacking the required training and declare that the miner is a hazard to himself and to others. The miner(s) identified must be removed immediately from the mine until the appropriate training is given.

Accident and Recovery. In the event of an accident at a mine, the Mine Act authorizes a MSHA inspector to take all appropriate actions, including the issuance of withdrawal orders during rescue and recovery operations and during accident investigations (Mine Act, Sections 103[j], [k]). Following an accident, the most commonly issued order is Section 103(k), which serves to preserve the accident scene while an investigation into the cause(s) of the accident proceeds. A Section 103(k) withdrawal order is also used to control an operator's recovery operations. This is different from other withdrawal orders in that no penalty is associated with it because it is not issued as the result of a violation.

Pattern of Violations. MSHA has promulgated "pattern of violations" regulations pursuant to Section 104(e) of the Mine Act. This section requires MSHA to give written notice to a mine operator who has a pattern of violations designated as significant and substantial (S&S) (Mine Act, Section 104[e][1]). (The concept of S&S is discussed in more detail later.) The regulations permit the issuance of withdrawal orders to operators that exhibit a pattern of noncompliance with a safety standard, demonstrating the operator's disregard for the health and safety of miners. MSHA's regulations are found at Part 104 of Title 30 to the Code of Federal Regulations (CFR). Fortunately, to date, this onerous enforcement tool has not been commonly used.

Civil Penalties Issued to Operator for Violation of a Standard

A mine operator who receives a citation or withdrawal order is subject to a maximum civil penalty assessment of \$60,000 per violation (Mine Act, Section 110[a]). Typically, the penalty amount is first proposed by MSHA's Office of Assessments, using the six general criteria set forth in Section 105(b)(1)(B) of the Mine Act and the penalty assessment formulas in 30 CFR Section 100.3(a):

1. Appropriateness of the penalty to the size of the business of the operator charged
2. Operator's history of previous violations
3. Whether the operator was negligent
4. Gravity of the violation
5. Demonstrated good faith of the operator in attempting to achieve rapid compliance after notification of a violation
6. Effect of the penalty on the operator's ability to continue in business

MSHA may also assess higher penalties against a mine operator with an excessive history of violations. An operator's overall history of violations is considered every time a violation is assessed. Penalty points are calculated on the basis of the average number of assessed violations per inspection day for the preceding 24-month period. If a mine operator has an excessive history of violations, it will affect the penalty amount assessed for all future enforcement actions, including those that are non-S&S.

Special Assessments

If MSHA determines that the regular penalty assessment scheme would not yield an appropriate penalty, the Office of Assessments is authorized to disregard the formula and propose a special assessment. This new penalty must be supported with narrative findings by the Office of Assessments based on the penalty assessment criteria. The following categories of violations are reviewed to determine whether a special assessment will be proposed:

- Involving fatalities and serious injuries
- Resulting from an unwarrantable failure (i.e., constituting more than ordinary negligence) to comply with mandatory health and safety standards
- Operating a mine in the face of a closure order
- Failing to permit an authorized representative of the labor secretary to perform an inspection or investigation
- Involving individuals who are personally liable under Section 110(c) of the Mine Act
- Involving an imminent danger
- Discriminating under Section 105(c) of the Mine Act
- Involving an extraordinarily high degree of negligence or gravity or other unique aggravating circumstances

Special Findings

S&S

When investigating a possible violation, an inspector will note, on MSHA's enforcement action form, the level of negligence he or she believes attributable to the operator for the existence of the violation: none, low, moderate, high, or reckless disregard. In addition, the inspector is required to assess the gravity of the alleged violation or the degree of hazard or risk posed by the alleged violation. The term S&S indicates that the alleged violation is of a more serious nature in terms of gravity. Because the Mine Act did not define S&S, it was left to the Review Commission to do so in contested cases:

[A] violation is of such a nature as could significantly and substantially contribute to the cause and effect of a

mine safety or health hazard if, based upon the particular facts surrounding that violation, there exists a reasonable likelihood that the hazard contributed to will result in an injury or illness of a reasonably serious nature. (*Secretary of Labor v. Cement Division, National Gypsum Co.*, 3 FMSHRC 822, 825 [1981]).

As a result, in order to sustain an S&S violation, the labor secretary must prove four conditions: (1) that a mandatory safety standard was violated; (2) that a discrete safety hazard contributed to the violation; (3) the reasonable likelihood that an injury will result; and (4) that the injury will be of a reasonably serious nature.

Unwarrantable Failure

The term *unwarrantable failure*, set forth in Section 104(d) of the Mine Act, refers to the degree of an operator's fault or negligence in causing a violation. Although the term is not defined in the Mine Act, the Review Commission has described it as "aggravated conduct, constituting more than ordinary negligence" (*Emery Mining Corp. v. Secretary of Labor*, 9 FMSHRC 1997 [1987]). Only those violations of a mandatory health or safety standard characterized as resulting from "high" negligence or "reckless disregard" can be issued as an unwarrantable failure.

A MSHA inspector may look at the following factors to determine whether an unwarrantable failure exists:

- The length of time the violation existed before it was discovered by the inspector
- Whether the violation should have been discovered by the operator during required inspections or routine travel or equipment use
- Whether there was a failure to report the condition as required by company policy
- Whether the violation was caused by unforeseeable conduct on the part of a miner
- Whether the facts support a conclusion of aggravated conduct beyond a mere finding that the operator should have known about the violation.

A citation for an S&S violation, caused by the operator's unwarrantable failure to comply with a standard, is issued under Section 104(d)(1) of the Mine Act. The initial citation commences the "d-chain" or "withdrawal order chain." Each time thereafter, during the same inspection or any subsequent inspection within 90 days that an unwarrantable failure violation is observed, an unwarrantable failure order will be issued. After the initial Section 104(d)(1) citation is issued, the subsequent unwarrantable failure orders issued in the chain do not have to be S&S. The operator stays on the d-chain until there is an intervening "clean" inspection (i.e., no unwarrantable failure orders) of the entire mine.

JURISDICTION

The Mine Act's enforcement provisions extend to almost every aspect of the mining industry, and its jurisdictional scope has been broadly interpreted by the courts. The Mine Act's jurisdiction encompasses

Each coal or other mine, the products of which enter commerce, or the operations or products of which affect commerce, and each operator of such mine, and every miner in such mine shall be subject to the provisions of this Act. (Mine Act, Section 4)

The two key terms that must be defined when determining whether the Mine Act applies to a workplace or to an employer are "mine" and "operator."

Definition of "Mine"

Section 3 of the Mine Act defines a *mine* as

(A) an area of land from which minerals are extracted in nonliquid form or, if in liquid form, are extracted with workers underground, (B) private ways and roads appurtenant to such area, and (C) lands, excavations, underground passageways, shafts, slopes, tunnels and workings, structures, facilities, equipment, machines, tools, or other property including impoundments, retention dams, and tailings ponds, on the surface or underground, used in, or to be used in, or resulting from, the work of extracting such minerals from their natural deposits in nonliquid form, or if in liquid form, with workers underground, or used in, or to be used in, the milling of such minerals, or the work of preparing coal or other minerals, and includes custom coal preparation facilities.

The definition includes related milling operations, including the alumina refining process, mine development, rehabilitation activities, and exploration work at an established mine.

MSHA has jurisdiction over lands, equipment, and structures used or to be used in the preparation of the coal. Congress intended that "what is considered to be a mine and to be regulated under this Act be given the broadest possible interpretation" (S. Rep. 95-1919, at 14 [1977], reprinted in 1977 U.S.C.C.A.N. 3401, 3414). (See also, *Marshall v. Stoudt's Ferry Preparation Co.*, 602 F.2d 589, 591-92 [3d Cir. 1979], cert. denied, 444 U.S. 1015 [1980].)

Consequently, the federal courts and the Review Commission have relied on the Mine Act's legislative history to include activities not commonly associated with the definition of a mine. For example, a mine operator's off-mine site central supply shop that warehoused materials and supplies was defined as a mine (*Jim Walter Resources, Inc.*, 22 FMSHRC 21 [2000]).

Further interpretation and explanation of what is considered a mine, and therefore under MSHA's jurisdiction, can be found in an interagency agreement between MSHA and the Occupational Safety and Health Administration (OSHA) (OSHA/MSHA Interagency Agreement *Federal Register* 44, no. 22827 [April 17, 1979, amended February 22, 1983]).

The OSHA/MSHA Interagency Agreement delineates areas of inspection responsibility, sets up a procedure for determining general jurisdictional questions, and provides for coordination between the two agencies in areas of mutual interest.

Definition of "Operator"

When Congress promulgated the Mine Act, it expanded the 1969 Coal Act's definition of *operator* to include independent contractors. Section 3(d) defines an operator as "any owner, lessee, or other person who operates, controls, or supervises a coal or other mine or any independent contractor performing services or construction at such mine" (Mine Act, Section 3[d]). Just as Congress intended a mine to be defined broadly, it also intended that operator be broadly interpreted.

With the inclusion of independent contractors in the definition of operator, the courts and the Review Commission have supported MSHA's authority to cite virtually anyone working on the mine site. For example, a company that provided elevator maintenance services at a mine was found to be a mine operator, because its work was sufficiently related to the extraction of ore to qualify it as an operator and it had a "continuing presence" at the mine (*Otis Elevator Co. v. Secretary of Labor*, 921 F.2d 1285 [D.C. Cir. 1990]). The elevator company's employees worked between 6 to 20 hours

at the mines and their work was performed in the center of mining activities on equipment that was essential to the mining process.

With the Mine Act's expanded definition of an operator, MSHA has the authority to issue enforcement actions directly to an independent contractor for violations committed by the contractor or its employees. According to MSHA, this authority does not, however, lessen the production-operator's overall responsibility for compliance with the Mine Act and the standards. MSHA has taken the position that the production-operator is in the best position to coordinate the contractor's activities and monitor safety performance, because the production-operator has the overall knowledge and daily control of the mine operation. (See *MSHA Program Information Bulletin No. P94-14*, May 20, 1994.) MSHA characterizes this as "overlapping compliance responsibility."

As a result, MSHA may issue citations or orders to both the independent contractor and to the production-operator for a violation. MSHA's guidelines state that it is appropriate to issue an enforcement action to the production-operator for a violation committed by the independent contractor or its employees under any of the following situations:

- When the production-operator has contributed by either an act or by an omission to a violation in the course of an independent contractor's work
- When the production-operator has contributed by either an act or omission to a violation committed by an independent contractor
- When the production-operator's miners are exposed to the hazard
- When the production-operator has control over the condition that needs abatement

PROMULGATION OF REGULATIONS

Regulations

The Mine Act has a complex and comprehensive structure to safeguard the health and safety of miners. One aspect is the specific mandatory health and safety standards that are set forth in Titles II and III of the Mine Act. The Mine Act refers to them as "interim mandatory safety and health standards," recognizing that legislated interim standards should evolve to provide increased safety and, when necessary, to address changes in mining technology.

The Mine Act authorizes the labor secretary to use two procedures for changing the interim standards. The first is notice-and-comment rulemaking, through which the secretary can promulgate new, industry-wide safety or health standards, provided that any new or revised standard does not "reduce the protection" afforded by a mandatory standard. The second procedure, discussed later in this chapter, allows individual mining companies or miners' representatives to "petition for modification" of a particular standard.

Procedures for rulemaking are set forth in Section 101 of the Mine Act. The rulemaking provisions of the Administrative Procedures Act, 5 U.S.C. Section 553, are also applicable. Both acts set forth time frames to follow. Proposed rules promulgating, modifying, or revoking mandatory health or safety standards must be published in the *Federal Register*. Persons interested in providing comments or data are provided an opportunity to submit written information and may also request a public hearing. The labor secretary is required to publish in the *Federal Register* notification of the standards for which comments were received. If a hearing is requested, the secretary must propose a schedule for the hearing, and interested persons must be allowed to present oral or written comments at the hearing. In addition, the secretary is authorized to use a subpoena to compel the attendance of any witnesses (Mine Act, Sec-

tion 101[a][2] and [3]). After the close of the comment period, if no hearing was held, the secretary is required to publish what action will be taken regarding the standard and the reasons for the action. If the secretary decides to delay taking any action or making a decision about the standard, the reasons for the delay must be published in the *Federal Register*. Unless another time frame is specified, a new standard is effective following publication in the *Federal Register*.

Any person (or legal entity) that is adversely affected by a standard promulgated pursuant to Section 101 may file a petition challenging the validity of the standard. The challenge may be filed in either the federal district court for the District of Columbia or the federal court for the circuit where the person who is adversely affected resides or has a principal place of business. Importantly, no objection that has not been raised with the secretary can be considered by a court unless good cause is shown for the failure to raise the objection (Mine Act, Section 101[d]).

The MSHA standards that have been promulgated are found at Title 30 of the CFR. The safety and health standards applicable to surface metal and nonmetal mines are in Part 56. Those applicable to underground metal and nonmetal mines are found in Part 57. Many of the standards in Parts 56 and 57 are identical or substantially similar. Because the standards are primarily performance based, the determination of whether a standard has been violated in a specific situation is typically whether a reasonably prudent person, familiar with mining and the specific circumstance at issue, would find that a violation exists. Other regulatory compliance standards in Title 30 include:

- Part 40—Miners' Representative Requirements
- Part 41—Legal Identity Requirements
- Part 46—Training Requirements for Shell Dredging, Sand, Gravel, Surface Stone, Surface Clay, Colloidal Phosphate, and Surface Limestone Mines
- Part 47—Hazard Communication
- Part 48—Training Requirements for All Underground and Surface Coal and Metal/Nonmetal Mines, except mines covered by Part 46
- Part 50—Accident and Injury Investigation and Reporting
- Part 62—Noise Regulations

Petition for Relief from Requirements of Mandatory Standards

The second procedure for modifying mandatory standards is through a petition for relief from the requirements of mandatory standards. An operator is not permitted to petition for modification of a health standard. The procedure for modifying mandatory safety standards is provided in Section 101(c) of the Mine Act, which allows relief from the application of a safety standard under two circumstances:

1. If the secretary determines that an alternative method guarantees the same measure of protection to the miners as the standard
2. That the application of such standard to the mine will result in a diminution of safety to the miners

Procedures governing petitions for modification are found in the regulations at 30 CFR Part 44. After MSHA receives the petition, a notice is published in the *Federal Register*, and interested persons have 30 days to submit comments or information. In addition, MSHA conducts an investigation into the merits of the petition, which typically includes an on-site examination. MSHA inspectors from the local district office then prepare an investigation report and a draft of their proposed decision. After the investigation,

the appropriate MSHA official issues a proposed decision and order, which becomes final in 30 days unless a hearing is requested. (The MSHA official who issues the proposed decision and order is either the deputy administrator for Coal Mine Safety and Health or the deputy administrator for Metal and Nonmetal Safety and Health.)

Hearings are held before ALJs, not the Review Commission. If no hearing is requested, the terms and conditions of the MSHA official's decision and order become enforceable as a mandatory standard.

A request for a hearing must be filed within 30 days after service of the proposed decision and order and is forwarded to the Department of Labor's chief ALJ for assignment. The ALJ who is assigned to the matter holds a hearing and issues a decision. A party has 30 days to file a notice of appeal of the ALJ's decision with the assistant secretary of labor for mine safety and health. The assistant secretary may affirm, modify, or set aside the decision. For purposes of judicial review, the decision by the assistant secretary is the final agency action. It may be appealed to the U.S. Court of Appeals in the jurisdiction where the mine is located or appealed to the U.S. Court of Appeals for the District of Columbia.

Mine Site Plans

The Mine Act requires operators to submit mine-specific plans addressing such topics as roof control and ventilation. (See, e.g., Mine Act, Sections 302[a], 303[o].) Mine plans are intended to be site-specific plans, taking into consideration the conditions and mining systems of each particular mine, and are enforceable by MSHA as if they were a regulation. Some mine plans are subject to periodic review and/or approval by MSHA. If a mine operator fails to operate in accordance with a plan, the Mine Act requires that the mine operator be cited for that violation (Mine Act, Section 104[a]). As a result, a mine operator should be cautious about agreeing to plan terms about which it has reservations.

The labor secretary has promulgated standards that require a mine operator to develop and adopt mine plans. For example, some of the regulations applicable to nonmetal mines that require plan adoption are the following:

- 30 CFR Section 48.3—training
- 30 CFR Section 49.4—alternative mine rescue capabilities
- 30 CFR Part 62—hearing conservation
- 30 CFR Part 47—hazard communication

SPECIFIC MINE ACT ENFORCEMENT TOOLS

Enforcement Actions against Mine Operators

The types of citations that may be issued to a mine operator include the following:

- Citation for a violation of the Mine Act, mandatory health or safety standard, rule, order or regulation (Mine Act, Section 104[a]).
- Unwarrantable failure citation for a violation that could significantly and substantially contribute to a health or safety hazard. This is the first link in the closure order chain based on unwarrantable failure findings (Mine Act, Section 104[d][1]).
- Citation for exceeding respirable dust standard at underground coal mines (Mine Act, Section 104[f]).

The various orders of withdrawal that may be issued to a mine operator include the following:

- Failure to abate a Section 104(a) or Section 104(d)(1) violation in the time period given (Mine Act, Section 104[b]).
- Unwarrantable failure violation issued subsequent to Section 104(d)(1) citation during same inspection or within 90 days

after issuance of Section 104(d)(1) citation (Mine Act, Section 104[d][1])

- Unwarrantable failure violation issued during a subsequent inspection, after a Section 104(d)(1) order was issued, assuming that no intervening inspection of the mine in its entirety has disclosed further unwarrantable failure violations (Mine Act, Section 104[d][2])
- Pattern-of-violations order issued within 90 days after Section 104(e)(1) pattern notification is given to the operator if violation is found that could significantly and substantially contribute to a health or safety hazard (Mine Act, Section 104[e][1])
- Pattern-of-violations order issued after the Section 104(e)(1) order is issued when a violation is found that could significantly and substantially contribute to a health or safety hazard, assuming that no intervening inspection of mine in its entirety has disclosed further S&S violations (Mine Act, Section 104[e][2])
- Order issued when there is a failure to comply with respirable dust standard by the end of time granted in Section 104(f) citation at underground coal mine (Mine Act, Section 104[f][1])
- Order issued when miners have not received requisite safety training (Mine Act, Section 104[g][1])
- Order issued when an imminent danger is present, defined as a condition or practice that can reasonably be expected to cause death or serious physical injury before it can be abated (Mine Act, Section 107[a])
- Order that may be issued to take action deemed appropriate to supervise and direct rescue and recovery work following an accident (Mine Act, Section 103[j])
- Order issued to ensure safety of persons following an accident and to preserve evidence (Mine Act, Section 103[k])

Civil Penalties Associated with Enforcement Actions against Mine Operators

A director, officer, or agent of a corporate operator who knowingly authorizes, orders, or carries out a violation of a mandatory health or safety standard or who fails to comply with an order issued under the Mine Act or included in a final decision under the Mine Act may be subject to civil or criminal penalties (Mine Act, Section 110[c]). Criminal and civil penalties are generally pursued as a result of special investigations conducted by MSHA to uncover willful and knowing violations of the Mine Act. (See the Special Investigations section of this chapter for more information.)

Section 110(c) is most commonly utilized against management employees, including section supervisors, mine supervisors, safety directors, and other managers of corporate operators engaged in day-to-day mining operations. For purposes of assessing a civil penalty against an individual, "knowingly" means knowing or having reason to know (*Freeman United Coal Mining Co. v. FMSHRC*, 108 F.3d 358 [D.C. Cir. 1997]).

Section 110(c) subjects individuals to "the same civil penalties" that may be imposed on mine operators. However, when assessing civil penalties against individuals, the penalty assessment factors are based on the individual, not the operator; for example, in connection with the size criterion, the inquiry is of the individual's income and net worth.

Criminal Penalties

The Mine Act also allows for a variety of criminal penalties. The provisions of Section 110(c) may be used to pursue either criminal

sanctions or civil fines against agents, officers, and directors, depending largely on the nature of the violation and the evidence. Whether a civil or criminal sanction is imposed rests with MSHA's discretion, with input from the Justice Department. However, because conviction for a criminal act requires proof beyond a reasonable doubt, only those violations with evidence of intentional conduct are pursued criminally.

Under the Mine Act, criminal penalties can be imposed against operators for knowing and willful violations of mandatory health and safety standards (Mine Act, Section 110[d]). In the context of criminal liability, "knowingly" has been defined as an act done voluntarily and intentionally, and not because of mistake, accident, or other reason (*United States v. Jones*, 735 F.2d 785 [4th Cir.], cert. denied, 469 U.S. 918 [1984]). An operator who willfully violates mandatory health or safety standards, or who knowingly violates any order issued pursuant to Section 104 or Section 107, faces a maximum fine of \$25,000, imprisonment up to 1 year, or both for the first conviction. For subsequent convictions, a maximum fine of \$50,000, imprisonment up to 5 years, or both may be imposed.

In addition, the Mine Act allows for criminal sanctions for any person who provides unauthorized advance notice of mine inspections (maximum \$1,000 fine, imprisonment for up to 6 months, or both) or who knowingly makes a false statement, representation, or certification in any application, record, report, plan, or other document filed or required to be kept under the Mine Act (maximum \$10,000 fine, imprisonment for up to 5 years, or both) (Mine Act, Sections 110[e], [f]).

Special investigations are conducted under the general inspection authority of the Mine Act (Section 103[a]). Impeding a MSHA special investigation may constitute obstruction of an agency proceeding and includes witness influence, intimidation, and false statements made to investigators (18 U.S.C. Section 1505 [2004]). Other potential criminal acts relevant to the special investigation process include, but are not limited to, conspiracy (18 U.S.C. Section 371 [2004]), mail fraud (18 U.S.C. Section 1341 [2004]), bribery (18 U.S.C. Section 201 [2004]), concealment of material facts (18 U.S.C. Section 1001 [2004]), and obstruction of a federal criminal investigation (18 U.S.C. Section 1510 [2004]).

Contest of Citations and Penalties

An operator may contest a citation or order, and the associated penalty, by filing a contest with the Review Commission. There are three main methods to initiate review:

1. File a notice of contest under Section 105(d) within 30 days of issuance, modification, or termination of a citation or order issued under Section 104
2. File an application for review pursuant to Section 107(e)(1) within 30 days of issuance, modification, or termination of any order issued under Section 107(a)
3. File a contest of a civil penalty assessment by notifying the labor secretary within 30 days of receipt of the proposed penalty assessment of the operator's intent to contest the penalty

Once an operator initiates a contest of an enforcement action and/or the penalty, the resulting procedures and deadlines will vary, depending on whether it was a prepenalty contest or a contest of the proposed penalties. There are stringent deadlines to follow, as set forth in the Mine Act and the Review Commission's procedural rules found at 29 CFR Part 2700.

In addition, only certain parties may file specific protests. The parties to a contest or penalty proceeding include the operator, the

labor secretary, and any parties that are permitted to intervene. Affected miners or their representatives may intervene in a hearing by filing a written notice with the Review Commission. A miners' representative may only protest the length of the abatement time of a Section 104(a) citation and not the issuance or modification. However, miners or their representatives may challenge the issuance, modification, or termination of withdrawal orders issued under Section 104.

A hearing is held before an ALJ on the issues of fact and law raised by the parties. The ALJ administers the oath to witnesses, issues subpoenas, rules on offers of proof and objections, receives relevant evidence, disposes of procedural requests, and generally regulates the hearing. Often, the ALJ will ask questions of the witnesses for purposes of clarification. The parties may seek to file written posthearing briefs or may make closing arguments at the hearing. The ALJ will issue a written decision that includes findings of fact and conclusions of law. The ALJ has the authority to vacate or uphold a citation, modify the negligence and gravity findings, and reduce or increase the penalty amount.

Any person adversely affected by the ALJ's decision may file a petition for discretionary review with the Review Commission within 30 days of the decision. Because this review is discretionary, the affirmative vote of at least two of the Review Commissioners is required within 40 days of the decision in order for the review to be heard by the commission. Alternatively, the Review Commission may vote to grant review of the decision on its own motion, or *sua sponte*, within 30 days of the ALJ's decision. If review is granted, a person may file a motion to intervene in the proceeding within 30 days of the Review Commission's direction for review. Intervention is also subject to the Review Commission's discretion. The Review Commission's rules set forth the time frames in which parties must file the appropriate written documents relating to the review process.

Any person adversely affected by an order of the Review Commission may file a petition to modify or set aside the order with the U.S. Court of Appeals for the circuit in which the violation occurred or with the District of Columbia Circuit Court of Appeals. This petition for review must be filed within 30 days of issuance of the Review Commission's order. The procedural requirements for a petition for review are set forth in the Federal Rules of Appellate Procedure.

INSPECTIONS AND INVESTIGATIONS

The Mine Act grants broad inspection powers to MSHA, essentially authorizing three types of inspections: (1) routine or regular, (2) spot, and (3) those performed pursuant to a miner's complaint (Mine Act, Sections 103[a], 103[i], 103[g]).

Regular inspections are conducted to determine compliance with the Mine Act and MSHA regulations. MSHA is required to make a complete inspection of all underground mines at least four times a year and of all surface mines at least two times a year (Mine Act, Section 103[a]). Spot inspections are conducted when a mine releases excessive amounts of methane, if the mine has experienced a methane or gas ignition that resulted in a death or serious injury, or when there is some other hazardous condition (Mine Act, Section 103[i]). Finally, a miner may request an inspection if he or she believes there is a condition that violates the Mine Act or MSHA regulations, or that an imminent danger exists.

A common thread that runs through each type of inspection is the intent of Congress, declared in the legislative history of the Mine Act, that the labor secretary be permitted to conduct inspections in the absence of a search warrant. The U.S. Supreme Court has ruled that warrantless inspections under the Mine Act generally do not violate an operator's Fourth Amendment rights (*Secretary of*

Labor v. De wey, 452 U.S. 594 [1981]). Warrantless inspection authority also extends to seizure of records required to be kept under the Mine Act. Courts have been reluctant, however, to extend the inspection exception to records not specifically required to be maintained by the Mine Act. While an operator may make other records available, doing so is voluntary and amounts to a waiver of any privacy rights.

Accident Investigations

In addition to MSHA's broad inspection powers, the Mine Act requires MSHA to investigate the causes of accidents and "other occurrence[s] relating to health or safety" (Mine Act, Section 103[b]). In light of this, every mine operator should have a plan to deal with a serious accident, fatality, explosion, or other disaster.

MSHA has promulgated detailed regulations (found at 30 CFR Part 50) for accident investigations and record keeping in connection with accidents. The regulations require immediate notification to MSHA if an accident occurs. In addition, a mine operator must preserve the accident scene until MSHA has completed its investigation, "except to the extent necessary to rescue or recover an individual, prevent or eliminate an imminent danger, or prevent destruction of mining equipment" (30 CFR Section 50.12). The Part 50 regulations also contain detailed requirements for the reporting and record keeping of occupational illnesses and injuries.

If an accident occurs, MSHA is required to do what is necessary to protect lives, including directing rescue and recovery operations and issuing appropriate safety orders (Mine Act, Sections 103[j], 103[k]). During the course of an investigation of an accident or other occurrence, MSHA, after notice, may also hold public hearings, administer oaths, and issue subpoenas to compel attendance, testimony, and the production of relevant documents and items (Mine Act, Section 103[b]). However, MSHA rarely resorts to these formal hearing mechanisms and prefers a more informal approach to investigations. The agency typically conducts an investigation, issues enforcement actions, and generates a report that outlines its findings and conclusions. The focus of MSHA's investigation is to determine the cause of an accident and prevent recurrences.

The primary device MSHA uses to gather information is witness interviews. Because the interview process is informal and non-custodial, MSHA is not required to inform the witness about the right against self-incrimination (*Miranda v. Arizona*, 384 U.S. 436 [1966]). MSHA usually does not administer oaths and prefers to tape-record the interviews and to have the witness sign a statement. The decision to submit to an interview is voluntary and a witness may refuse to be interviewed or to permit tape recording of the interview. A witness also has the right to refuse to sign a written statement or summary of the interview.

Special Investigations

Investigations under Section 110(c)

As discussed earlier, the Mine Act gives MSHA authority, under certain circumstances, to impose civil penalties and criminal fines against individual managers and corporate operators. These are determined through a process called a special investigation. Actions that are reviewed for possible special investigation include the following:

- All Section 104[d] unwarrantable failures, S&S citations, and orders
- All fatal and serious injury accidents
- All Section 107(a) imminent danger orders that involve a violation of a mandatory standard

Each investigation case file submitted by a MSHA investigator recommending individual civil or criminal penalties must include specific evidence to support the following:

- That the operator is a corporation
- That the violation created was properly cited
- That the violations created a hazard that posed a "high degree of risk" to miners
- That there was an agent of the operator with knowledge of the violation and that persons were exposed to the condition

Targets of special investigations are typically officers, directors, and agents of the company, including supervisors, safety directors, and others involved in the day-to-day supervision of all or part of the mining operations and/or miners. MSHA's special investigation procedures can be summarized as follows:

- The qualifying enforcement action is reviewed in the district office for referral.
- The district manager recommends whether to refer the enforcement action for a special investigation to MSHA's Arlington, Virginia, headquarters.
- If a special investigation is opened, the special investigator obtains the enforcement file and/or the accident investigation file.
- Interviews with all involved persons, witnesses, and potential targets or defendants are voluntary. Investigators generally contact employees directly.

Individuals are never required to talk to a special investigator and have the following rights during a Section 110(c) investigation:

- To counsel or other representatives prior to and during speaking with an investigator
- To speak with an investigator alone
- To refuse to answer certain questions
- To discontinue an interview at any time
- To refuse to have an interview tape recorded
- To refuse to sign a statement taken by the investigator

Investigations under Section 105(c)

The purpose of Section 105(c) of the Mine Act is to protect miners, job applicants, management level employees, and representatives of miners from retaliation for engaging in protected activity. Additional information regarding Section 105(c) is provided later in this chapter.

Under Section 105(c), an initial complaint of discrimination must be filed with MSHA within 60 days after the alleged violation occurs. Within 15 days of receiving the complaint, MSHA special investigators begin researching the allegations in the complaint. The MSHA special investigators may interview the complaining party, the operator, and others having relevant information. No operator can attempt to hinder any investigation of a Section 105(c) complaint or prevent management employees from talking with the special investigator. Front-line managers are the usual and likely targets of investigations and discrimination claims because of their constant interaction with miners in matters involving production and safety.

If MSHA determines that a complaint is valid, a formal complaint will be filed with the Review Commission within 30 days of MSHA's determination. The complaint is filed on behalf of the miner with notification to the operator and the complaining party.

If MSHA determines that a complaint is not valid, the complaining party may pursue his or her own complaint before the Review Commission. The complaint must be filed within 30 days of the complaining party's receipt of MSHA's written determination that

no violation occurred. An operator must respond to a formal complaint within 30 days after receipt. Failure to answer within 30 days may result in the entry of a final order against the operator.

INJUNCTIONS

The Mine Act authorizes MSHA to pursue a civil action seeking relief, including temporary or permanent injunctive relief or a restraining order, in federal district court (Mine Act, Section 108). MSHA may pursue a civil action if a mine operator does one of the following:

- Refuses to comply with an order or decision issued under the Mine Act
- Interferes with, hinders, or delays MSHA from carrying out its duties under the Mine Act
- Refuses to allow an inspection or investigation
- Refuses to provide other information or access to a mine.

However, an operator cannot seek an injunction in advance of enforcement action. Operators are precluded from this avenue of relief by the Mine Act's administrative review scheme under which challenges to enforcement actions must be reviewed first by the Review Commission and then by an appropriate court of appeals.

POSTING AND RECORD-KEEPING REQUIREMENTS

Posting Requirements

As part of the regulatory scheme of the Mine Act, mine operators are required to provide certain information to MSHA and to the miners. Mine operators must post on the mine bulletin board all citations, orders, notices, and decisions that are required by the Mine Act or regulations to be given to the operator, pursuant to the posting requirements of Section 109(a) of the Mine Act. Mine operators are required to maintain the bulletin board at the mine office or "at a conspicuous place near an entrance of" the mine; the above-described documents are to be posted "immediately;" and the posted documents must be "easily visible" and "protected against damage by weather and against unauthorized removal" (Mine Act, Section 109[a]). The Mine Act does not state how long such information must remain posted. Because the Mine Act does not specifically require that decisions and orders of the Review Commission or courts be given to the operator, they do not have to be posted to comply with Section 109(a) (*Secretary of Labor v. Thunder Basin Coal Co.*, 18 FMSHRC 582 [1996]). However, it is common that the decision or order requires that it be posted at the mine site.

In addition to the requirements of Section 109, a number of standards have specific posting requirements. For example, the miners' representatives must file specific information with MSHA's district manager and provide a copy of that information to the operator. The mine operator is then required to post this information on the mine bulletin board (30 CFR Section 40.4). Generally, mine operators must also post the training plan (30 CFR Sections 46.3[g], 48.3[n], and 48.23[n]). A comprehensive discussion of all of the posting requirements under Title 30 of the CFR is beyond the scope of this chapter. Mine operators should review the specific regulations to determine if any document is required to be posted.

Record-Keeping Requirements

MSHA may make requests and demands for a broad range of company records. Many of these records are written by a management official in an effort to analyze the cause of an event and/or prevent its recurrence and are expected to be private. Unfortunately, in the hands of an opposing party, some records may be utilized to support allegations against the company or individual managers.

Records requested by MSHA inspectors may include

- Injury- and illness-related documents (workers' compensation records, insurance forms, medical reports, personnel records, supervisory reports of accidents and incidents, and safety department audits or evaluations)
- Operations records (production and progress reports, maintenance records, equipment manuals, equipment purchase orders, mine policy or procedural memos, and mine logs or summary books used for shift-to-shift communication)

Required records and those kept in the ordinary course of business may be used to establish heightened negligence under the Mine Act by establishing *actual or constructive* knowledge of hazards and violations. Therefore, a record retention policy should be considered for mine-site implementation that retains required records for mandated time frames and limits retention of other records to their useful life. Such a record retention policy will assure compliance with legal requirements and prevent the accumulation of old records. Such a record retention policy will assure compliance with legal requirements and prevent the accumulation of old records, which may jeopardize the company's interest if discovered during litigation.

MINERS' RIGHTS

The Mine Act contains a wide range of protections and noncontractual rights for miners. Some are quite complex. Following is a brief overview of miners' rights under the Mine Act.

Protection against Discrimination

In general, Section 105(c) states that no person may discharge or otherwise discriminate against a protected individual who exercises any of the rights set forth in the Mine Act, or who files or makes a complaint regarding a safety or health hazard. In order to prevail, the protected individual must establish that he was discriminated against because he engaged in some type of statutorily protected activity. If a finding of discrimination is made, the Mine Act authorizes the Review Commission to take whatever steps are appropriate to return the miner to his former position, including, but not limited to, rehiring or reinstatement with back pay and interest.

In cases brought by the miner through his private counsel under Section 105(c)(3), an award of attorney's fees and costs in prosecuting the claim may be granted. An award may include fees incurred through the appellate stage and are usually calculated by multiplying the prevailing rate in the community for similar work by the number of hours worked.

A discrimination claim brought pursuant to Section 105(c) has three essential elements: (1) protected activity, (2) adverse action, and (3) causal nexus between the protected activity and the adverse action. In other words, in order to prevail, a complaining miner must establish that he suffered adverse action because he engaged in some type of statutorily protected activity.

Initially, the complaining miner must make out a *prima facie* case of discrimination by establishing that the protected activity in some way motivated the adverse action. The burden then shifts to the operator to demonstrate that the activity was not protected, or that the activity was protected but did not in any way lead to the adverse action, or that a "mixed motive" was involved. In mixed-motive cases, the adverse action is caused, at least in part, by the unprotected activity which, by itself, would have caused the mine operator to take the alleged adverse action. The majority of discrimination cases involve such mixed-motive determinations.

If the claim involves a discharge or suspension, an application for temporary reinstatement may be requested by the labor secretary

and heard, on an expedited basis, within 10 days after the request is filed, to determine whether the miner's complaint was "frivolously brought." If no hearing is requested, the ALJ will review the secretary's application and required accompanying affidavit supporting the secretary's findings before making a decision on temporary reinstatement. If the ALJ concludes that the complaint is not frivolously brought, temporary reinstatement may be ordered. A temporary reinstatement order either granting or denying the relief may be appealed to the full Review Commission but will not stay the effect of the order unless directed by the Review Commission.

Protected Work Refusals

Miners have the right to refuse to work in unusually hazardous conditions. Although this right is not specifically spelled out in either the Mine Act or MSHA regulations, its basis may be found in the legislative history and in the Review Commission and court decisions interpreting that history. The exercise of this right may be particularly troublesome because of its effect on production and control of the work force. A four-part test has evolved for determining whether a work refusal is protected activity under Section 105(c). (The right was first recognized by the Review Commission in *Secretary of Labor ex rel. Pasula v. Consolidation Coal Co.*, 2 FMSHRC 2786 [1980], *rev'd sub nom. Consolidation Coal Co. v. Marshall*, 663 F.2d 1211 [3d Cir. 1981].)

That test requires a miner to have (1) a good faith (2) and reasonable belief (3) that a hazard exists, (4) which is ordinarily communicated to the mine management.

Defining the extent or degree of the perceived hazard necessary to support a protected work refusal has proved to be an evolutionary process and fact-dependent. The facts of each case obviously will vary, and whether a hazard exists sufficient to support a work refusal is determined on a case-by-case basis. But when issues are raised by a miner concerning a hazard, and management adequately addresses the concerns, a protected work refusal will not be supported.

Rights to Contact MSHA

A miner has the right to request a MSHA inspection if the miner believes there is a violation of the Mine Act or a health or safety standard, or that an imminent danger exists (Mine Act, Section 103[g]). MSHA is required to conduct an inspection as soon as possible and to withhold the name of the miner who filed the complaint. As a result of a Section 103(g) investigation, MSHA can issue enforcement actions.

Transfer Rights

The Mine Act has two provisions regarding a miner's transfer rights, Sections 101(a)(7) and 203(b). Section 101(a)(7) addresses promulgation of mandatory health or safety standards for toxic substances and warning of hazards and symptoms. If it is determined that "a miner may suffer material impairment of health or functional capacity by reason of exposure to the hazard covered by the mandatory standard," then the miner is to be "removed from such exposure and reassigned" (Mine Act, Section 101[a](7)). MSHA has not promulgated any standards under this section of the Mine Act.

On the other hand, Section 203 provides for medical examinations of miners working in coal mines. If a miner shows evidence of lung disease, the miner is to be given the option of transferring to a position in another area of the mine where the concentration of respirable dust is lower. A miner so transferred "shall receive compensation for [work in the new area of the mine] at not less than the regular rate of pay received by him immediately prior to his trans-

fer" (Mine Act, Section 203[b](3)). MSHA's regulations that address miners' transfer rights are codified at 30 CFR Part 90.

Walk-Around Pay Rights

The Mine Act provides that mine operators and representatives of miners have the right to accompany MSHA inspectors during inspections or investigations (Mine Act, Section 103[f]). MSHA has promulgated standards regarding this issue at 30 CFR Part 40 to encourage miner participation in the process. Section 103(f) states that if a miner's representative is an employee of the mine operator, the representative "shall suffer no loss of pay during the period of his participation in the inspection." Case law addresses the complexities under this provision, such as what the operator is required to do when separate MSHA inspection teams are carrying out different activities.

Compensation When Mine Is Idled by Withdrawal Order

Under the Mine Act, miners who are idled by withdrawal orders are entitled to certain statutorily mandated levels of compensation. Section 111 of the Mine Act provides for three classes of idlement compensation. These classes are differentiated by the types of closure orders that caused the idlement and affect the level of compensation.

1. Miners idled by any closure order issued during their shift are entitled to receive pay for up to the remainder of the shift plus up to 4 hours into the next shift if the order remains in effect.
2. Miners idled by a Section 104 or 107 closure order predicated on a violation of a mandatory health or safety standard are entitled to receive pay for the period idled for up to 1 week.
3. Miners working while any closure order is in effect, who should have been withdrawn from the area affected by the order, are entitled to full compensation for the time worked, in addition to their regular pay, from the date of the order until the date of compliance, vacation, or termination.

Any order issued under the first or second classification requires that miners be compensated at their regular rate of pay for the period idled by the order or until the end of the shift, whichever is shorter. If an order continues in effect on the next shift, miners on that shift idled by the order must be paid for the period idled, up to a maximum of 4 hours. According to Section 111, the right to this compensation accrues regardless of whether the violation is sustained following review.

The provision for compensation of up to 1 week described in the second classification is commonly referred to as "augmented" compensation. It is only available after the withdrawal order is final. If the order is contested and invalidated, the augmented compensation is not paid, but the basic compensation is still payable (i.e., remainder of the shift plus up to 4 hours). However, the validity of the order of withdrawal cannot be challenged for the first time in the compensation proceeding. Consequently, if an operator believes that an order was issued erroneously, the challenge must be made in a contest or penalty proceeding under Section 105(d), or, in the case of a Section 107(a) order, in an application for review filed within 30 days.

Right to Participate in Litigation

Miners are entitled to participate in the litigation of citations, penalty assessments, and orders issued under the Mine Act, Section 105[d]. Miners may also seek and receive party status in litigation (see 29 CFR Section 2700.4[a][b]). However, miners and their representatives do not have the right to contest citations (*UMWA v. Secretary of Labor*, 5 FMSHRC 807 [1983], *aff'd* 725 F.2d 126 [D.C. Cir. 1984]).

Right to Paid Training

The Mine Act requires mandatory training of miners (Mine Act, Section 115). New miners who have no prior underground experience must receive at least 40 hours of training before they work underground. Training must include several topics, including the statutory rights of miners under the Mine Act, hazard recognition, and the health and safety aspects of the tasks to which they will be assigned. New miners who will work at surface operations must receive at least 24 hours of training that covers generally the same topics covered for new underground miners. Newly hired, experienced miners also must receive training, which includes mine-specific information, such as escape ways, mine transportation, and emergency medical procedures. In addition, all miners must receive a minimum of 8 hours of refresher training at least once every 12 months. When a miner is assigned to a new task, he must be provided with task training.

The training requirements are set forth in 30 CFR Parts 46 and 48. The standards contain detailed requirements, including those for a training plan approved by MSHA. Part 46 requirements apply to all persons at shell dredging, sand, gravel, surface stone, surface clay, colloidal phosphate, and surface limestone mines. These are generally small mines with fewer employees than those covered by Part 48. Part 48 applies to all underground and surface coal and metal and nonmetal mines, except for those covered by Part 46. The standards also require mine operators to maintain records of miner training.

Additional Rights

The Mine Act has other specific provisions for miner participation. Those include

- The right to participate in inspections
- The right to contest the reasonableness of the length of time for abatement specified in a citation (Section 105[d])
- The right of an any representative of miners to apply for reinstatement, modification, or vacation of an imminent danger order (Section 107[e][1])

SUMMARY

The Mine Act is a complex piece of legislation that covers all mine operators and miners throughout the United States and that holds mine operators responsible for the safety and health of miners. It sets mandatory safety and health standards, mandates miners' training requirements, prescribes penalties for violations, and enables inspectors to close dangerous mines. The Mine Act requires that MSHA inspect all mines each year and requires or authorizes additional inspections and investigations to ensure safe and healthy work environments for miners.

To promote compliance with the provisions of the act and its safety and health standards, all violations found during inspections and investigations must be cited. All violations are subject to civil penalties and must be corrected within the time frames established by MSHA. In addition, the act provides for either civil penalties against individuals for "knowing" violations or criminal sanctions against mine operators that "willfully" violate safety and health standards. The Mine Act gives individual miners, as well as their representatives, and job applicants many specific employment rights. It requires MSHA to

- Provide compliance assistance through development of safety and health training programs in cooperation with industry and labor
- Test new mining equipment
- Work with other agencies to advance safety and health research programs
- Compile and analyze accident, injury, and illness data to better address serious workplace hazards

Environmental Law for Industrial Minerals and Rocks

Kurt E. Blase and James P. Ryan

This chapter summarizes federal environmental laws and regulations with significant effects on mining, processing, and use of industrial minerals. It is intended as a primer for mining engineers who are not attorneys but need a basic understanding of the federal environmental requirements that apply to their operations. It provides a comprehensive summary of the major environmental requirements and issues that a mining engineer is likely to face in the industrial minerals sector, though not in great detail. Although this chapter may not answer all pertinent questions, it should provide the information necessary for a productive search.

This chapter is organized along media lines, with separate discussions of air quality, water quality, waste disposal, and product regulation. The focus is primarily on summaries of existing regulatory requirements, though relevant legislative developments and judicial opinions are discussed as warranted. Where possible, references that provide more detailed information are listed. The preference is for references that are generally available, such as the Code of Federal Regulations (CFR) and the *Federal Register*. The conclusion of the chapter discusses some of the more controversial environmental issues in the industrial minerals sector at the time of this writing.

The discussion is limited to federal laws, but states have complementary and parallel laws that can differ from federal requirements and must always be consulted as well. As a general rule, state environmental programs are organized in the same manner as federal requirements, and the standards or other substantive requirements contained in federal laws and regulations are the minimum requirements for state programs. In most cases, however, federal law permits states to adopt more stringent requirements if they choose to do so. Accordingly, the federal requirements discussed in this chapter should be viewed in most cases as a minimum, and the possibility that more stringent requirements may be applied under state law should always be considered.

Where a state is proposing to adopt requirements more stringent than federal law, several legal remedies may be available. The state's proposal must be permissible under federal law, and it must also be consistent with state law. Some states have adopted state laws that prohibit deviation from federal requirements. Others have not gone to that length but also have not adopted state laws that expressly allow deviation from federal law. In states where state law expressly allows deviation from federal requirements, the proposal must be consistent with the applicable state law and must have a reasonable factual basis.

AIR QUALITY

The current federal Clean Air Act (CAA) was initially adopted in 1970 and substantially amended in 1977 and 1990 [42 U.S.C. § 7401 *et. seq.* (2004)]. An earlier statute, the Air Quality Act of 1967, directed the Department of Health and Human Services (then the Department of Health, Education, and Welfare) to set federal ambient air quality standards based on public health concerns and divided the United States into air quality regions for purposes of attaining the standards. Impatient with the states' progress under the 1967 act, Congress adopted the 1970 act to "take a stick to the states" to improve air quality. Shortly after the 1970 act was adopted, President Nixon created the federal Environmental Protection Agency (EPA), by Executive Order, to oversee administration of the CAA and, ultimately, the other environmental laws adopted in the early 1970s and discussed throughout this chapter. The 1977 amendments strengthened various portions of the 1970 CAA and added new authority to address air quality in areas that meet or exceed the ambient standards ("prevention of significant deterioration") and air quality in areas not attaining the ambient standards ("nonattainment areas"). The Clean Air Act Amendments of 1990 (CAAA) again strengthened the prior provisions and added new provisions governing acid deposition control, operating permits, and stratospheric ozone protection.

The CAA provisions of greatest interest in industrial minerals sectors are the following: (1) ambient air quality standards and state implementation plans, (2) prevention of significant deterioration (PSD) and nonattainment rules, (3) new source performance standards, (4) hazardous air pollutant (HAP) standards, (5) permitting, (6) mobile source standards, and (7) enforcement. These are discussed in the sections that follow.

Ambient Standards and State Implementation Plans

The backbone of the federal CAA is the program for national ambient air quality standards (NAAQS), and state/regional implementation of those standards, first adopted in the 1967 act. Under the current act (CAA), the NAAQS are set by EPA, but the plans for attaining the standards are adopted by the states, subject to EPA oversight and approval.

Sections 108 and 109 of the CAA govern establishment of NAAQS for so-called conventional pollutants (42 U.S.C. §§ 7408 and 7409). As a general matter, these are pollutants that are found pervasively in the air throughout the country and have

Table 1. National ambient air quality standards

Pollutant	Primary NAAQS	Secondary NAAQS
SO _x	0.030 ppm (annual mean) 0.14 ppm (24-hour average)	0.5 ppm (3-hour average)
Particulate matter, PM ₁₀ *	150 µm/m ³ (24-hour average) 50 µm/m ³ (annual mean)	Same† Same
Particulate matter, PM _{2.5} *	15 µm/m ³ (annual mean) 65 µm/m ³ (24-hour average)	Same Same
CO	9 ppm (8-hour average) 35 ppm (1-hour average)	None
Ozone	0.12 ppm (1-hour average) 0.08 ppm (8-hour average)	Same Same
NO ₂	0.053 ppm (annual mean)	Same
Pb	1.5 µg/m ³ (quarterly average)	Same

* There are currently two types of standards for particulate matter (PM): one covers particles with diameters in the range of 0–10 µm (PM₁₀), and another for particles with diameters in the range of 0–2.5 µm (PM_{2.5}; also known as *fine particulate*). At the time of this writing, EPA is preparing to revise these standards, as discussed further in text.

† Indicates the secondary value is the same as the primary value.

been demonstrated to cause adverse health or environmental effects as a result of chronic exposure. EPA is to maintain a list of pollutants that are present in “ambient air” as a result of “diverse mobile or stationary sources” and that “cause or contribute to air pollution which may reasonably be anticipated to endanger public health or welfare” (42 U.S.C. § 7408(a)).* For each of these, EPA must develop “air quality criteria” that “reflect the latest scientific knowledge useful in indicating the kind and extent of all identifiable effects on public health or welfare which may be expected from the presence of such pollutant in the ambient air” (42 U.S.C. § 7408(a)). Thus, the pollutants for which ambient standards have been developed are often referred to as *criteria pollutants*.

Based on the air quality criteria, EPA must set primary standards at levels that, “allowing an adequate margin of safety, are requisite to protect the public health” (42 U.S.C. § 7409 (b)). Secondary standards must be set at levels “requisite to protect the public welfare from any known or anticipated adverse effects” (42 U.S.C. § 7409 (b)). “Welfare” is defined to include effects on all aspects of the environment, including “economic values” and “personal comfort and well being” (42 U.S.C. § 7602(h)). EPA also is directed to develop information on control technologies for conventional pollutants (42 U.S.C. § 7408(b)). A number of guidance

documents on control techniques for various mining segments and processes are available on EPA’s Web site (www.epa.gov).

The NAAQS are codified in EPA’s regulations at 40 CFR Part 50, which includes appendices containing detailed federal reference methods for determining compliance with the standards. Table 1 gives the primary and secondary standards applicable at the time of this writing.

Section 109(d) of the CAA requires EPA to review the ambient standards at least every 5 years and revise them if necessary. The ozone and particle standards are now being revised. Once an area has attained the 1-hour ozone standard, it no longer applies and the area is governed by the 8-hour standard (40 CFR 50.9(b)). In reviewing each ambient standard, EPA issues a revised Criteria Document that contains the updated scientific basis for the standard, and a revised Staff Paper that applies legal and policy considerations to the science in the Criteria Document to recommend revisions to the standard, if appropriate. Several drafts of these materials are generally made available for public review and comment, and for review by EPA’s Clean Air Scientific Advisory Committee. The Criteria Document and Staff Paper are excellent sources of detailed scientific and legal information about the ambient standards and the pollutants they address, as are the preambles to the *Federal Register* notices in which EPA proposed and adopted the standards.

The measures necessary for attainment of the ambient standards are specified in State Implementation Plans (SIPs). Section 110 of the CAA requires states to adopt plans adequate for attainment and maintenance of the ambient standards in the state. There are specific deadlines for attainment of the primary standards and the secondary standards must be attained “as expeditiously as practicable.” States generally use detailed emissions inventories to construct regional and state wide emissions “budgets” for emissions from stationary and mobile sources. The combination of the budgets for mobile and stationary sources must be demonstrated to meet the standards, and the SIP will include the emission limits and other emission controls necessary to ensure that emissions stay within the budgets. As a general rule, site-specific emission limits for existing stationary sources must be based on reasonably available control technology (RACT). EPA has issued RACT guidelines for many categories of sources that are available through EPA’s Web site. Although EPA cannot consider costs or other economic factors in setting the ambient standards, costs can be considered in developing source-specific emission limits in SIPs based on RACT. The SIP development documents compiled by state air quality agencies are an excellent resource for detailed information on the emission limits and budgets applicable at a particular site. SIPs must be revised as necessary when standards change or it becomes clear that the current measures in the SIP are not adequate (or not necessary) to ensure attainment of the standards.

EPA is required to approve SIPs and SIP revisions, and has adopted detailed regulations for doing so (40 CFR Part 51). EPA’s files on proceedings to approve SIPs or SIP revisions, generally located at the relevant EPA regional office, are also good sources of information on the basis for SIP requirements. If EPA disapproves a SIP or SIP revision, and the state fails to make the necessary corrections, the state will lose its authority to implement that portion of the SIP and EPA will impose a Federal Implementation Plan (FIP) provision. EPA’s regulations for FIPs are codified at 40 CFR Part 52.

PSD and Nonattainment

The CAA contains special requirements for areas that do not meet the ambient standards (nonattainment areas, Part D) and areas that exceed the ambient standards (PSD, Part C). The general idea is to require rapid progress toward attainment in nonattainment areas,

* The act does not define ambient air, but it is defined in EPA’s regulations as “that portion of the atmosphere, external to buildings, to which the general public has access” (40 CFR 50.1(e)). Thus, it is possible to create “non-ambient air,” in which the national standards do not apply, by denying public access to company property. This company property rule, in conjunction with the purchase of surrounding land, has been relied on by some large mining operations to a void applicability of the standards in areas near mines or mineral processing facilities where compliance would be difficult. Regulators historically have frowned on this approach but have been forced to allow it in the face of sound evidence that public access to the land is in fact denied. For a good discussion of the company property rule, see 49 *Fed. Reg.* 10946 (March 23, 1984) (sulfur dioxide plan for Kennecott Utah smelter). The definition of ambient air also has been relied on to mark the jurisdictional boundaries for occupational (Occupational Safety and Health Administration [OSHA]), Mine Safety and Health Administration (MSHA) and environmental (EPA) regulation at mining facilities.

and to keep air quality from deteriorating in areas that are attaining the standards.

EPA's PSD regulations are contained in the Part 51 regulations for SIP approvals (40 CFR 51.166) and are quite complex. Most states simply parrot these requirements in their SIPs and related state regulations. The regulations that apply under FIPs are similar (40 CFR 52.1029). PSD goals are attained by two types of requirements: (1) construction permits for new or expanded facilities and (2) air quality "increments" that limit deterioration and act as substitutes for the ambient standards. Attainment areas are placed into one of three classes: Class I, the most pristine areas; Class II, areas in which some deterioration (and hence some development) is allowed; and Class III, areas in which the most deterioration is allowed. For each class, increments have been established for PM, SO₂, and NO₂. The increments are expressed as the "maximum allowable increase above baseline." For example, the PM₁₀ increments (in µg/m³) are

	Class I	Class II	Class III
Annual:	4	17	34
24-hour:	8	30	60

The state adopts the classification for an area. Certain types of areas, such as national parks that exceed 6,000 acres and wilderness areas that exceed 5,000 acres, must be designated as Class I. All other areas are initially designated as Class II but can be redesignated by the state. When states attempt to reclassify areas that are near federal lands, the federal land manager generally plays a significant role. The PM increments historically have played a major role in limiting mine expansion, particularly for large mines in arid western regions. The PSD requirements, including permitting requirements, should be reviewed carefully in connection with any new mining or mine expansion project.

The provisions for nonattainment areas in Part D of the CAA were amended substantially in 1990 and are now quite complex. There are now specific nonattainment requirements for specific criteria pollutants. In general, they classify nonattainment areas as "moderate," "serious," or "severe," with escalating requirements for each classification. The primary requirements are to reduce emissions sufficiently to produce attainment within specified time periods, and to attain interim benchmarks that demonstrate "reasonable further progress." This involves a continuous "ratcheting down" of the SIP emissions budgets until the interim and final budgets are achieved. Special requirements also apply to construction permits for new or expanded sources in nonattainment areas. For facilities in nonattainment areas, the specific SIP provisions and underlying documents should be consulted.

New Source Performance Standards

Section 111 of the CAA requires EPA to adopt minimum standards of performance for new sources in major industrial categories, known as new source performance standards (NSPSs). The NSPSs generally are implemented in construction permits. NSPSs are emission standards that are based on the "best available technology adequately demonstrated." The underlying policy is that the most cost-effective time to install or upgrade emission controls is when a facility is initially built or is renovated in some manner for production purposes.

EPA's NSPS regulations are codified in 40 CFR Part 60. The standards apply to new, reconstructed, and modified sources. A source is modified if it undergoes a physical change or change in the method of operation that actually or potentially increases emissions of any regulated air pollutant. A source is reconstructed if the

cost of renovation exceeds 50% of the cost of a new unit. Under these rules, NSPSs will be applied to a modified source, even without a potential increase in emissions, if the source is reconstructed. On the other hand, if the renovation results in an emissions decrease, NSPSs will not apply as long as the facility has not been reconstructed. There are also a number of exemptions, including routine maintenance, an increase in the hours of operation, changes in ownership, and pollution control projects. An unusual aspect of NSPSs is that they apply to facilities that are constructed, reconstructed, or modified after the NSPS is proposed, whereas most standards do not apply until final standards have been adopted.

EPA's Part 60 regulations include NSPSs for most types of major industrial facilities. The standards are updated periodically as new technologies become available. EPA's regulations include NSPSs for metallic and nonmetallic mineral processing plants, calciners and dryers in certain mineral industries, lime-manufacturing plants, and phosphate rock plants, among other types of facilities that may be relevant to industrial minerals operations. The standards for nonmetallic mineral processing plants in 40 CFR Part 60, Subpart OOO, are representative. They apply to the following "affected facilities" in fixed or portable plants that crush or grind a list of non-metallic minerals: crusher, grinding mill, screening operation, bucket elevator, belt conveyor, bagging operation, storage bin, enclosed truck, and railcar loading station. Stack emissions of PM from these facilities are limited to 0.05 g/dscm and 7% opacity. Fugitive emissions are limited to 10% opacity, with some exceptions. Detailed requirements for monitoring, testing, record keeping, and reporting also are imposed.

Air Toxics Standards

Section 112 of the CAA provides for establishment by EPA of national emission standards for HAPs. These are not ambient air quality standards but source-specific emission standards that apply to categories of sources that emit HAPs. Unlike the conventional pollutants subject to the ambient standards, which are pervasive but harmful primarily in chronic exposure situations, HAPs are substances that are emitted primarily in local "hot spots" (such as near an industrial facility) and can be acutely toxic.

The original version of Section 112, enacted in 1970, required EPA to set health-based standards that provide an "ample" margin of safety (as opposed to the "adequate" margin required for NAAQS) for all acutely toxic pollutants and sources that emit them. The 1970 provision proved extremely difficult to implement, and only a few standards (known as NESHAPs, national emission standards for hazardous air pollutants) were set under that provision. They remain applicable and are codified in 40 CFR Part 61. One of them applies to arsenic emissions from primary copper smelters and essentially requires use of primary and secondary hooding systems in smelters where the quantity of arsenic in the feed exceeds a specified level. Other NESHAPs apply to uranium mines, mills, and tailings piles, and facilities containing asbestos.

The need to revise the HAP provisions was a primary driving force behind the 1990 CAAA, and Section 112 was revised extensively. It now contains a list of more than 400 HAPs for which standards may be set. EPA has authority to revise the list administratively. The list includes asbestos, fine mineral fibers (average diameter 1 µm or less), and a number of metals considered to be toxic, in addition to numerous other organic and inorganic chemicals and compounds. EPA is to set emission standards for categories of industrial facilities that include "major sources" of one or more listed pollutants. A major source is one that emits 10 tpy or more of any single listed pollutant, or 25 tpy or more of a combination of listed pollutants. EPA is allowed to change the se major

source thresholds for specific pollutants by rule. The source is any single facility or a group of facilities located within a contiguous area and under common control (the so-called co-location rule). Unlike the operating permit scenario, discussed later, fugitive emissions are counted in the major source determination for HAPs.

EPA's emission standards for various categories of industrial facilities that emit HAPs are codified in 40 CFR Part 63. The standards are set in two phases: (1) an initial technology-based standard is set on the basis of EPA's determination of the maximum available control technology (MACT); and (2) within 10 years after setting the initial standard, EPA is to determine whether additional measures should be required on the basis of an assessment of the residual risk that remains after the technology-based standards are implemented. Costs can be considered in setting MACT standards, but standards for new sources must reflect at least the degree of control that is achieved in practice by the best-controlled similar source. MACT standards for existing sources must reflect a degree of control that is an average of the best performing sources in the category.

HAP standards are implemented in SIPs and permits. All of EPA's current standards are MACT standards, and the agency is only just beginning the residual risk determinations for the initial MACT standards, while continuing to establish MACT standards for categories of sources not yet regulated. The CAAA provides specific deadlines for establishment of MACT standards that have, in some cases, been implemented through court orders that place EPA on a specific timetable. If EPA misses an applicable deadline to set standards for a source category, states are to set source-specific standards for sources within the category that are located in the state. Section 112 also requires EPA to establish a program for prevention of accidental releases of HAPs, and the agency has adopted implementing regulations at 40 CFR Part 68.

Most types of industrial minerals operations are not subject to MACT standards at present, though EPA may develop them in the future. Existing standards that may be of interest apply to facilities that manufacture bricks and structural clay products (subpart JJJJ), clay ceramics (subpart KKKK) or refractory products (subpart SSSS), and to asphalt plants (subpart LLLL).

Permitting

Before the 1990 amendments, the CAA required construction permits for major new sources or source modifications in PSD and non-attainment areas but did not require existing sources to obtain operating permits. Most states developed operating permit programs of some type, and Congress added a federal operating permit program to the act in 1990 (Title V). Both programs are summarized.

Construction Permits. The construction permit program, also known as new source review (NSR), is generally implemented by states with substantial review by EPA regional offices. EPA's NSR regulations are part of the SIP regulations and are codified at 40 CFR 51, subpart I (SIPs), and 40 CFR 52.1026 (FIPs).

The construction permit program applies to "major sources" that are newly constructed or modified in a manner that produces a significant net increase in emissions. As with NSPSs, modification is defined as any physical change or change in the method of operation of the source, including the exemptions described in the NSPS discussion. A construction permit is required, however, only if the modification produces a "significant net" emissions increase, unlike the NSPS program, which applies to a modification that produces *any* emissions increase. There are two major differences between the NSPS and permitting programs in this respect. First, the permit program applies only where there has been a "net" increase, meaning that an increase in emissions from one piece of

equipment at a source (for example, a crusher) could be offset with a corresponding decrease from another piece of equipment at the same facility (e.g., a conveyor belt or loading station). This is called "bubbling," and it is allowed in determining the applicability of permitting requirements but not NSPSs. Second, a permit is not required unless the net emissions increase is "significant." EPA's regulations define "significant" increases for criteria pollutants and certain HAPs. Accordingly, under the scenario described, if the crusher were modified in a manner that increases emissions (or reconstructed, as explained in the NSPS discussion), the modified crusher would need to comply with NSPSs. If corresponding emission reductions from a conveyor belt are sufficient to avoid a significant net emissions increase, however, no construction permit would be required. EPA has published detailed guidance on bubbling and emissions trading that should be consulted in making these determinations.

In addition, federal construction permits are required only for a "major source" or a "major modification" of a major source. These are defined in EPA's regulations (e.g., 40 CFR 51.166(b)(1)). In general, a major source is any source with the potential to emit 250 tpy or more of any regulated pollutant, except for a list of source categories that are considered to be "major" if potential emissions are 100 tpy or more. The list includes lime plants, phosphate rock plants, large boilers, and other types of sources that might be found at industrial minerals operations. A major modification is one that creates a major source or causes a significant net emissions increase from a major source. The major source thresholds for HAPs are 10 tpy of any single HAP or 25 tpy of a combination. Under the co-location rule, the source is any stationary source or group of sources located on contiguous property and under common control.

The construction permit regulations also define "source" as facilities within the same two-digit Standard Industrial Classification (SIC) code. Thus, at an integrated facility that contains, for example, a mine, a concentrator, and a smelter all under common control, the mine/concentrator unit is one source and the smelter is a different source, meaning that emission from all could not be aggregated for purposes of determining the major source emissions threshold. The SIC code rule is also used in the operating permit regulations, but it does not appear in the HAP regulations.

In determining emission rates from particular pieces of equipment for determining the major source, EPA and states generally rely on the EPA compilation of emission rates known as AP-42 (available from <http://www.epa.gov/ttn/chief/ap42/>). That document should be consulted for emission rates that are likely to be used by permitting authorities, absent site-specific data. In the past, many of the emission rates in AP-42 were notoriously inaccurate, often based on one or two data points taken years ago from out-moded facilities. In recent times, however, various segments of the mining and mineral processing industries have made it a priority to ensure that the AP-42 emission rates for facilities at their operations are accurate and up to date. Many states also use AP-42 emission rates to compute operating permit fees. As specified in the preamble to AP-42, site-specific emission rates can be used in lieu of the AP-42 rates provided they are scientifically sound.

As a matter of federal law, fugitive emissions from mining and mineral processing operations generally are not counted in the major source determination. EPA's regulations contain a list of fugitive emissions sources for which fugitive emissions are counted, and it includes some facilities that may be found at industrial minerals operations (40 CFR 51.166 (b)). Under Section 302 (j) of the CAA, EPA is not permitted to count fugitive emissions unless it has determined by rule that they should be counted for the particular

source category at issue. The list of fugitive emissions sources includes any source subject to an NSPS adopted before August 7, 1980. That does not include metallic or nonmetallic mineral processing plants, because both of those NSPSs were adopted after that date. From time to time, EPA has considered a "Section 302(j) rule-making" to add these facilities to the list, but has not yet done so. The only category of facilities for which EPA has held such a rule-making is surface coal mines, which EPA decided not to place on the list of fugitive emissions sources. In practice, the rule against consideration of fugitive emissions often means that mining or mineral processing operations are not major sources that are required to obtain permits. This federal rule, however, can be overridden by state rules under which fugitive emissions are considered.

The substantive requirements for construction permits differ depending on whether the source would be located in (or significantly affect) a nonattainment area or a PSD area. Permits in nonattainment areas are governed by Section 173 of the CAA. The source is required to comply with the "lowest achievable emission rate" (LAER), which is generally determined by the state in accordance with EPA guidance that can be obtained from the EPA Web site. At a minimum, LAER must comply with any applicable NSPSs, in addition to any other control technologies or measures that may be relevant and available. The owner of the source also must obtain, from other sources in the area, an "emissions offset" under which the combined emissions of the new source and the other sources in the area are sufficiently reduced to show "reasonable further progress" toward nonattainment goals. Some of the nonattainment provisions in the act provide pollutant-specific permit and offset requirements. For example, the major source threshold for PM₁₀ in a "serious" nonattainment area is reduced to 70 tpy.

In addition, the owner of a source seeking a construction permit in a nonattainment area must certify compliance with all applicable regulations at other facilities under common control, and EPA must determine that the state is adequately implementing the SIP. The owner also must demonstrate that the benefits of the source outweigh the environmental costs. Provisions necessary to implement these requirements will be placed in permits generally issued by state permitting authorities subject to regional EPA review.

Permits in PSD areas are governed by Section 165 of the CAA as implemented in EPA's Part 51 regulations for PSD and NSR. The permit must contain conditions sufficient to ensure that the new or modified facility will not cause or contribute to NAAQS violations and will not cause exceedance of the applicable PSD increments, including those for any Class I areas that might be affected. Compliance with these requirements, and related requirements for source monitoring and other air quality impact analyses, often requires a year or more of advance air quality monitoring or modeling work.

PSD permits also must require use of the best available control technology (BACT). BACT is, at a minimum, compliance with applicable NSPSs, plus any additional level of control that the state may determine is a viable considering costs. The primary difference between BACT and LAER is that BACT is a "technology," whereas LAER can require other types of control measures as well. In concept, BACT is "NSPS plus," and LAER is "BACT plus." RACT, the level of control required for existing sources that are not newly constructed or modified (and therefore not subject to these NSR control requirements), can be something less than NSPSs, though it could also be NSPSs if the necessary technology is determined to be "reasonably available." Guidance for determining compliance with all of these various control requirements at particular sources is available on EPA's Web site.

Operating Permits. The federal operating permit program was added in 1990 to require all major sources to have operating permits in which all of the applicable air quality requirements in the SIP or in applicable construction permits are gathered in one place and kept current. It is primarily a state program subject to EPA approval, and EPA's regulations for approving state programs are codified in 40 CFR Part 70. Permits eventually will be required for some types of minor sources as well, and many states already have minor source NSR and operating permit programs.

Detailed requirements for operating permit applications, issuance, and renewal are presented in EPA's Part 70 regulations. The rules for determining major sources and consideration of fugitive emissions are the same as previously described with respect to construction permits. As a result of litigation filed by the mining industry over the original Part 70 rules, EPA has issued guidance indicating that the co-location rules cannot be used to require a permit for an unlisted source of fugitive emissions that would not otherwise be considered a major source that requires a permit. The guidance does not apply to construction permits and indicates that EPA may revisit this issue in the context of a Section 302(j) rulemaking.

Operating permits must be renewed periodically, and procedures for permit amendments following operational changes also are specified. Operating permits are not to impose any new substantive requirements, though state agencies often find ways to do so (e.g., updating requirements said to be outdated). In addition, permits must include monitoring requirements sufficient to ensure compliance, as regulated under EPA's compliance assurance modeling (CAM) rules codified at 40 CFR Part 64. Some state agencies use this requirement to impose new or revised monitoring provisions in operating permits. Permit applications must certify that the facility is in compliance with all applicable requirements or must include a compliance schedule for doing so. States are allowed to charge permitting fees that reflect the costs of administering the operating program. Fees often are assessed on the basis of the quantity of emissions, as determined by the emission rates provided in AP-42.

Mobile Sources

Under federal law, mobile source emissions that occur within a stationary source (e.g., heavy mining equipment) are not subject to regulation in stationary source permits and are not to be counted in determining the applicability of permit requirements. But state regulators often find creative ways to do so, and mobile source emissions must be examined as part of a National Environmental Policy Act (NEPA) analysis if it is required (as discussed further in the following sections). EPA has established, and is now in the process of updating, emission standards for heavy- and light-duty vehicles, heavy-duty diesel engines, and off-road engines. The purchase or use of equipment that meets the applicable standards is the primary consideration with respect to mobile source emissions at industrial minerals operations. In addition, use of such equipment can be limited by state mobile source emissions budgets.

Another mobile source requirement that can affect industrial minerals segments is "conformity." One of the conditions for release of federal funds for highway or transit projects is a requirement to demonstrate that mobile source emissions generated by the project (e.g., increased automobile emissions from expansion of a highway) would "conform" to the applicable state mobile source emissions budget. If not, no federal funding can be provided for the project. In recent years, antidevelopment groups have used the conformity rules effectively to delay road construction and other projects that cannot proceed without federal funding, with a significant effect on some industrial minerals sectors.

Enforcement

Section 113 of the CAA imposes civil penalties up to \$25,000 per violation per day for violations of the act or the implementing regulations. Criminal penalties, including imprisonment and fines under the federal criminal statutes, are provided for “knowing” violations, and for negligent release of a HAP that poses imminent danger. Intentional release of a HAP that poses imminent danger is punishable by imprisonment and fines up to \$1 million. EPA has issued civil and criminal penalty policies that specify how various mitigating factors will be taken into account in the assessment of penalties.

An EPA enforcement action begins with issuance of a Notice of Intent to initiate an investigation under Section 114 of the CAA. Companies or individuals who receive a Section 114 notice should involve experienced counsel as quickly as possible. If EPA believes, as a result of the Section 114 investigation, that a violation has occurred, a notice of violation will be issued. As a general rule, in civil cases, EPA will then commence an administrative enforcement action and attempt to negotiate a settlement. If a settlement is concluded, the terms will be embodied in a consent decree that will be entered as an order of the appropriate court. Typical settlement terms include compliance plans, remediation measures, and supplemental environmental projects (SEPs), in addition to penalties. A SEP is an environmental project that is not otherwise required by law and essentially is financed in lieu of penalty payments. Criminal cases are handled separately by EPA's Office of Criminal Enforcement.

If a settlement cannot be reached, EPA generally will initiate the administrative enforcement process before an administrative law judge at EPA. If the administrative process fails, or the penalty is very large, or injunctive relief is necessary, EPA will refer the case to the Department of Justice for prosecution in the appropriate federal court. In addition to these provisions, Section 303 of the CAA allows EPA to issue orders or bring civil actions to address actions believed to be causing imminent and substantial danger. In addition, Section 304 of the act allows private citizens to file enforcement actions if they have given 60 days' notice to EPA and the agency is not diligently prosecuting the action. Section 304 also allows private citizens to file actions to force EPA to perform non-discretionary actions under the act.

WATER QUALITY

The current federal Clean Water Act (CWA) was enacted in 1972 and substantially amended in 1987. It grew from the prior attempts of Congress to regulate waters that are “navigable in fact” under the Rivers and Harbors Act of 1899. The regulatory reach of the current act, however, extends far beyond such waters, as discussed in more detail in the text that follows. The primary focus of the 1972 act was establishment by EPA of technology-based effluent standards for categories of industrial sources and implementation of the standards in a national system of discharge permits. With adoption of the 1987 amendments, the focus has shifted to adoption of water quality standards designed to protect public health and aquatic ecosystems and development of permit terms necessary for compliance with the standards.

The primary components of the CWA are (1) effluent guidelines and standards; (2) water quality standards; (3) discharge permits; (4) “dredge or fill” permits; (5) oil spill responses; and (6) enforcement. These are discussed in the sections that follow.

Effluent Guidelines and Standards

Section 301 of the CWA requires EPA to establish technology-based effluent standards for a wide array of categories of industrial

facilities. The standards apply nationwide and are implemented in permits issued under the National Pollutant Discharge Elimination System (NPDES). The limits are designed to be technologically and economically feasible for the affected industry segment.

For conventional pollutants discharged to surface waters from existing sources, initial standards were to be based on the “best practicable technology currently available” (BPT), to be followed within a few years by new standards, generally more stringent, based on the “best conventional pollutant control technology” (BCT). For toxic pollutants, the standards are to be based on the “best available technology economically achievable” (BAT). Under Section 306 of the CWA, new source performance standards must be based on the “best available demonstrated control technology” (BDT). Sources that are “fundamentally different” from the facilities on which the standards were based may be eligible for a variance based on such differences.

EPA's national effluent guidelines and standards are codified in 40 CFR beginning at Part 400. Categories that are subject to standards and may be of interest in industrial minerals sectors include cement manufacturing (Part 411), phosphate manufacturing (Part 422), asbestos manufacturing (Part 426), mineral mining and processing (Part 436), centralized waste treatment (Part 437), ore mining and dressing (Part 440), transportation equipment cleaning (Part 442), and asphalt paving and roofing materials (Part 443). The background information documents compiled by EPA in setting these standards and the *Federal Register* notices proposing and promulgating the standards are excellent reference sources for understanding the basis for the standards and the details of the regulated processes.

Water Quality Standards

Water quality standards can be established by EPA or states. EPA has published federal guidance, available on the agency's Web site, on appropriate standards for some pollutants. Most applicable water quality standards are now set by states under state law.

Water quality standards serve two purposes: (1) they define the water quality goals for a specific body of water based on designated uses identified by the state; and (2) they are the basis for permit limits designed to make sure that the standards are not exceeded. Section 303 of the CWA requires states—or EPA if a state does not comply—to designate uses for all water bodies and stream segments in the state. Representative uses include industrial use, domestic use, recreation, and fish habitat, among others. The general goal of the act as stated in Section 101, however, is to ensure that all national waters are “fishable” and “swimmable” where this goal is attainable.

After the designated use of a water body has been established, ambient water quality standards are then imposed at levels necessary to maintain and protect the designated use. The standards can take several forms, including numeric concentration limits for specific substances, numeric toxicity levels, or narrative statements. In some cases, whole effluent toxicity (WET) tests are required that measure the effects of effluent on aquatic organisms in the receiving waters. In addition, EPA has adopted an antidegradation rule that requires protection of current uses (40 CFR 131.12). Water quality that exceeds an applicable standard cannot be degraded to the level of the standard absent social or economic justification.

Water quality standards are the “second wave” of protection under the CWA and increasingly drive permit limits. In many cases, the technology-based effluent standards that were adopted during the early years of the act assist in attainment of water quality standards but are not capable of producing full compliance and must be

augmented with additional permit conditions necessary to attain the applicable water quality standards.

Permitting

The CWA imposes strict liability for discharge of any pollutant by any person into the “navigable waters of the United States,” except in compliance with a valid discharge permit. Historically, EPA has interpreted this to extend to all surface water bodies that Congress can reach under the Commerce Clause of the Constitution, that is, all waters with any connection to interstate commerce. The act does not regulate groundwater, though the Safe Drinking Water Act provides for regulation of “sole-source aquifers” under some conditions, and state water quality or mining and reclamation laws often include requirements for groundwater protection.

In the 2001 case of *Solid Waste Agency of Northern Cook County v. U.S. Army Corps of Engineers*, S.Ct. No. 99-1178, however, the Supreme Court held that EPA’s jurisdiction under the act does not extend to isolated intrastate ponds or other state waters that do not affect interstate waters. The effect of this decision is to remove some isolated state waters from the purview of the federal program that previously were thought to be subject to the program. The precise scope of the Court’s decision remains a matter of debate within EPA and the Army Corps of Engineers, though more recent lower court decisions have generally interpreted the Supreme Court’s decision narrowly. It is likely to be some time before the precise effect of the Supreme Court’s decision is known, and Congress is considering legislation in reaction to the Court’s decision.

The CWA establishes two types of permits: (1) NPDES permits for discharges into navigable waters under Section 402; and (2) “dredge or fill” permits under Section 404. These are discussed in the following sections.

NPDES Permits

Permits under Section 402 are required for any “discharge of a pollutant” from a “point source” into the navigable waters of the United States. They are issued by EPA or by states with EPA-approved permit programs, which are now in place in most states. Permits contain discharge limits as necessary to comply with applicable effluent and water quality standards, monitoring and reporting requirements, and various “standard conditions.” The usual permit term is 5 years, after which the permit must be renewed, and amendment is required following significant changes in operations. EPA has issued extremely complex regulations for permit application, issuance, amendment, and renewal, codified at 40 CFR Part 122. Standards and criteria for permits are codified in Part 125.

There are two types of NPDES permits: (1) individual permits issued to a facility based on site-specific information, and (2) general permits that cover discharges from categories of industrial sources. A facility operator generally can choose between the two. For general permits, no application is required, but the operator must file a Notice of Intent to proceed under the general permit. In the past, general permits were used fairly widely at some mining or mineral processing operations. EPA recently revised the general permit for mining activities, however, and greatly reduced its utility for some operations. This action is currently subject to litigation.

Section 502 of the CWA defines “discharge” as “any addition” of a pollutant to regulated waters. The courts have generally focused on whether the activity introduces a pollutant from outside of the water body at issue. “Pollutant” is defined very broadly and can include temperature, fish or other organisms, or water of varying quality. A point source is a pipe, ditch, channel, tunnel, well, conduit, or other synthetic structure, excluding irrigation return flows and agricultural stormwater discharges. Stormwater

runoff is subject to special permit regulations codified in 40 CFR Parts 122–124.

Nonpoint-source pollution includes runoff from agricultural and silvicultural operations (crops, fields, forested lands) and runoff from mines; mining activities that release pollutants from discernible conveyances, however, are point sources. It can also include changes in flow or circulation caused by dams, levees, channels, or other diversions. The 1987 amendments added Section 319, which requires states to identify actions necessary to improve the quality of waters impaired by nonpoint-source pollution. In addition, Section 303 of the CWA, as amended in 1987, requires waters not protected by effluent limitations to be listed as impaired. For such waters, EPA or the states must establish total maximum daily loads (TMDLs) that apply to both point and nonpoint sources. A TMDL is the largest amount of pollution that a water body can receive daily without violating the applicable water quality standards. The objective of the TMDL program is to identify, for specific water bodies and locations, an appropriate division of water quality control efforts among point and nonpoint sources, and to impose related controls on both types of sources. In some cases, the existing requirements for point sources in permits will need to be strengthened. In many parts of the country, the effect of the TMDL program is only just beginning to be felt.

Under Section 307 of the CWA, special standards and permit requirements are applied to sources that discharge into publicly owned treatment works. These are called “pretreatment requirements,” and EPA’s regulations governing them are codified at 40 CFR Part 403.

Dredge or Fill Permits

Section 404 of the CWA requires issuance of permits for any dredging or filling operations that affect regulated waters. Section 404 permits are issued by the Army Corps of Engineers, in consultation with EPA. As with the NPDES program, discharge is defined broadly as any addition of pollutants. Dredged material is material excavated from water, including some fallback material. Fill material is material used to create dry land or alter the bottom elevation. This generally includes activities involving wetlands, which are defined as areas “inundated or saturated by surface or groundwater at a frequency and duration sufficient to support, and that under normal circumstances do support, a prevalence of vegetation typically adapted for life in saturated soil conditions” (33 CFR 328.3(b)). In 1998, a federal court invalidated the Corps’ so-called Tulloch rule, which required a permit for incidental fallback at mining and other operations. EPA and the Corps have interpreted that court’s decision very narrowly, however, and the issue remains uncertain and in litigation at this time.

As with the NPDES program, there are two types of Section 404 permits: (1) nationwide permits for classes of dredge-and-fill activities, and (2) individual permits. Nationwide Permit 44 (NWP 44), which governs mining activities, was revised and severely limited in 2002, including limitation to activities involving a half acre of wetlands or less. The NWP 44 that was issued in 2002 is currently in litigation. Nationwide permits include general provisions that require avoidance of adverse impacts where possible and mitigation where impacts are unavoidable. Permit provisions also include verification and state certification requirements, and some require preconstruction notice to the state or the Corps.

The Corps has adopted detailed regulations for individual permits, codified in 33 CFR Parts 325 and 327. The permit process includes NEPA and public interest review, and permits are required to include mitigation provisions to avoid, minimize, or compensate

for adverse impacts. An administrative appeal and veto process also is provided.

Oil and Hazardous Substances

Section 311 of the CWA, a precursor to the federal Superfund law, prohibits discharges of oil or hazardous substances into regulated waters in quantities that violate water quality standards or create a sheen or sludge. EPA's regulations for implementing this program appear in 40 CFR Part 112. They include requirements for development of spill prevention plans, reporting of spills, and reimbursement of removal or other cleanup costs.

Enforcement

Sections 309 and 505 of the CWA govern enforcement actions, which are similar to the actions permitted under the CAA as described earlier in this chapter. Administrative penalties up to \$12,000/day can be assessed by EPA, with a maximum of \$31,500 for informal proceedings and \$157,500 for formal proceedings. SEPs are allowed and mitigating factors are considered, including the gravity of the violation, the economic benefit the violation produced, prior violations, good faith, and ability to pay. Cases involving larger penalty amounts or injunctive relief are referred to the Department of Justice for prosecution in the federal courts.

Criminal penalties may be assessed for negligent violations (\$2,500 to \$25,000/day and imprisonment up to a year), knowing violations (\$15,000 to \$50,000/day and up to 3 years' imprisonment), and knowing endangerment (up to \$250,000 and 15 years' imprisonment for individuals and \$1,000,000 for organizations). Citizen suits can be filed against violators or EPA in cases where EPA or the state fails to prosecute diligently after receiving notice of a violation.

WASTE DISPOSAL

Congress enacted the Resource Conservation and Recovery Act of 1976 (RCRA) to establish a comprehensive federal program to regulate the handling of solid wastes. RCRA amended the Solid Waste Disposal Act and was the first substantial effort by Congress to establish a regulatory structure for the management of solid and hazardous waste. RCRA's primary goals are to protect human health and the environment from the potential hazards of waste disposal, to conserve energy and natural resources, to reduce the amount of waste generated, and to ensure that wastes are managed in an environmentally sound manner. In 1984, Congress enacted the Hazardous and Solid Waste Amendments (HSWA), which significantly expanded the scope and requirements of RCRA.

To achieve these goals, Congress established three distinct, yet interrelated programs under RCRA. Of those three programs, only two are relevant in the context of the mining industry. Those sections are Subtitle C, the hazardous waste program (42 U.S.C. § 6921–6939(b)), and Subtitle D, the solid waste program (42 U.S.C. § 6941–6949(a)). Subtitle C was implemented to address “cradle-to-grave” requirements for hazardous waste from the point of generation to the ultimate disposal and requires EPA to promulgate regulations to govern the treatment, storage, and disposal of these wastes. Subtitle C requires EPA to develop criteria to identify hazardous wastes and authorizes the agency to list particular wastes as hazardous according to certain enumerated criteria. Generally, wastes are considered hazardous under Subtitle C if they are listed as hazardous by the administrator of EPA or they are found to have one of four technical characteristics that make them hazardous. Those four characteristics are ignitability, corrosivity, reactivity, and extraction procedure (EP) toxicity, which EPA separately defined as the leaching of toxic residues into surrounding liquid.

Under Subtitle D of RCRA, states are allowed and in fact encouraged to use federal financial and technical assistance to develop comprehensive solid waste management plans in accordance with guidelines promulgated by EPA. EPA has authority under Subtitle D to promulgate criteria for classification of waste facilities as sanitary landfills or open dumps. Facilities can be classified as sanitary landfills only if there is no possibility that the facility poses a danger to health or the environment from deposits made at those sites. Subtitle D prohibits open dumping of potentially dangerous solid wastes and requires states to submit for EPA approval comprehensive solid waste disposal plans that include a prohibition of such unregulated dumping. Subtitle D of RCRA regulates only nonhazardous solid wastes and hence its requirements are less restrictive than those found in Subtitle C.

Regulation of Mining Wastes

Congress enacted Subtitle C to address the hazards of industrial and manufacturing process wastes. When RCRA was enacted, however, Congress recognized that it lacked sufficient information to bring mining wastes within the purview of Subtitle C. As a result, Congress included a statutory provision directing EPA to conduct a detailed study of mining waste to evaluate the potential danger to human health and the environment and, ultimately, whether such wastes should be subject to Subtitle C and the related regulatory scheme. The study provision mandates investigation into the following factors: the sources and volume of mining waste and the present disposal practices; alternative practices and costs of the alternatives; potential dangers to human health and the environment; possibilities for use of discarded material; and adequacy of state or other federal regulatory programs to meet the problem.

Notwithstanding the mandate of Congress concerning the study of mining waste and the deferral of regulation of such waste until the results of the study were evaluated, at the time Congress enacted Subtitle C of RCRA, there was no provision that permitted EPA to defer the regulation of mining waste until the study mandated by the statute was complete. As a result, EPA instituted a stopgap measure whereby in December 1978 it proposed regulations to govern hazardous waste under which mining waste from the extraction, beneficiation, and processing of ores and minerals would be considered “special wastes,” defined as wastes that were generated in high volumes but were considered low hazard. These high volume, low hazard special wastes were to be subject to separate standards from waste that otherwise fell within the scope of Subtitle C.

The new special wastes provision was abandoned by EPA in 1980 before it came into effect because EPA had narrowed the EP toxicity and corrosivity criteria for Subtitle C regulation, the anticipated result being that the special wastes would no longer qualify for stringent regulation under Subtitle C (i.e., they would no longer meet the criteria of wastes that were subject to Subtitle C). Certain mining waste streams from primary metal smelting and refining operations that satisfied the revised criteria for hazardous wastes, however—specifically, copper blowdown wastes, lead impoundment solids, and zinc wastewater sludges—were proposed to be listed as hazardous waste by EPA.

Shortly before these new regulations were to take effect, Congress enacted the Solid Waste Disposal Act amendments of 1980, which included what has come to be known as the Bevill Amendment. The Bevill Amendment added two key provisions to RCRA. First, in addition to extending the deadline on the study of mining waste required by RCRA, it added a new section that required EPA to conduct a comprehensive study of the adverse environment and health effects of the disposal and utilization of solid wastes from

the extraction, beneficiation, and processing of ores and minerals, including phosphate rock and overburden from uranium mining, among solid wastes from mining operations. Second, it required EPA to defer, for a period of at least 6 months after the completion of the studies, the imposition of the Subtitle C regulation on solid wastes that resulted from the extraction, beneficiation, and processing of ores and minerals. The Bevill Amendment also required EPA to determine whether regulation of those wastes under Subtitle C of RCRA was warranted. This determination had to be made by EPA within 6 months of the completion of the statutorily mandated study.

To incorporate the Bevill Amendment's exclusion of certain mining wastes from regulation under Subtitle C, and therefore maintain consistency between the statutory requirements and the EPA regulations, EPA published an amendment to its hazardous waste regulations in November 1980. The regulatory amendment tracked the language of the Bevill Amendment and extended the mining waste exclusion to apply to solid waste from the exploration, mining, milling, smelting, and refining of ores and minerals. Since it excluded smelting operations from the purview of Subtitle C, EPA also temporarily suspended the listing under Subtitle C of three of the hazardous waste streams that resulted from smelting operations: copper blowdown waste, lead impoundment solids, and zinc treatment sludges. EPA also went further and temporarily suspended the remaining three types of hazardous waste that resulted from smelter operations.

In 1984, Congress enacted the HSWA. These amendments strengthened the RCRA regulatory scheme and specifically gave EPA the flexibility to fashion Subtitle C standards for wastes from the extraction, beneficiation, and processing of ores and minerals. In particular, EPA was given the authority to modify the various standards for hazardous waste disposal under Subtitle C to take into account the special characteristics of such wastes.

Although the hazardous and solid waste amendments broadened EPA's authority to include its ability to regulate mining waste, it could not use its broadened authority until it completed the study required by the Bevill Amendment. The statutorily mandated deadline for the study was October 21, 1983, which EPA missed. As a result of its failure to complete the study, EPA was sued by a concerned citizens group in September 1984. The citizens group suit sought to have EPA either list aluminum pot liners as a hazardous waste, which would then be subject to regulation under Subtitle C of RCRA, or include those wastes in the required study. During that case, EPA indicated that it would reinterpret the mining waste exclusion to at removed certain smelting and refining wastes from the scope of Subtitle C, and since those wastes would again be subject to Subtitle C regulation, they would not be included in EPA's study of mining waste. Based on this representation by EPA, a federal court awarded judgment to the plaintiffs and ordered EPA to abide by the schedule it proposed. Specifically the court ordered EPA to propose its reinterpretation of the mining waste exclusion by September 30, 1985; to complete the studies mandated by the RCRA statute by December 31, 1985; and to take final action on the proposed reinterpretation by September 30, 1986. In keeping with the court-ordered timetable, in October 1985, EPA proposed to narrow the scope of the exclusion of mineral processing wastes from Subtitle C. EPA subsequently withdrew this proposal in October 1986.

Also in keeping with the court-ordered schedule, EPA submitted to Congress and published the statutorily required study on December 31, 1985. The study included an evaluation of, among other types of wastes, mining waste from the early processing stages of extraction and beneficiation as required by Subtitle C but did not include any study of processing wastes because those

wastes were the subject of EPA's proposed reinterpretation of the Bevill Amendment and would have ultimately come back within the regulatory purview of Subtitle C. Although the report estimated that 755 Mt of waste produced yearly by the nonfuel mining industry potentially qualifies as hazardous waste, it recognized and acknowledged that this figure was an overestimate because the conventional testing for EP toxicity—one indicator of whether a waste is a hazard under Subtitle C—did not reflect real conditions. A modified test revealed that no mining waste samples tested were in fact toxic.

Relying on the results from the modified testing method, EPA then concluded that mining waste was not hazardous and that it was not going to regulate mining waste under Subtitle C of RCRA. Although EPA acknowledged that some of the wastes generated from the two categories were clearly hazardous, it concluded that a large segment of the industry could not afford to manage and treat these wastes if they were regulated under Subtitle C. EPA indicated it would attempt to develop a regulatory program for these two types of waste under the less stringent Subtitle D of RCRA. Although EPA's determination was challenged in court, it was upheld (see *Environmental Defense Fund v. EPA*, 852 F.2d 1309 (D.C. Cir. 1988)).

In October 1986, EPA withdrew its proposed reinterpretation of the Bevill Amendment exclusions. EPA asserted that there was no standard for ascertaining specifically what a "high volume-low hazard" waste was in the context of "special wastes," and thus there were no criteria for distinguishing processing waste from nonprocessing waste. EPA simultaneously reaffirmed its 1980 interpretation of the Bevill Amendment exclusions of processing wastes from regulation under Subtitle C. EPA was again sued on the ground that its decision was arbitrary and capricious. This time the court awarded judgment to the plaintiffs, requiring EPA to regulate smelting waste under Subtitle C (see *Environmental Defense Fund v. EPA*, 852 F.2d 1316 (D.C. Cir. 1988)). Subsequent to this decision, EPA engaged in a rulemaking process, the results of which were to list certain smelting wastes as "hazardous wastes" that were not exempt from regulation under Subtitle C of RCRA.

Mining on Federal Land

The policy governing mining on federal land is laid out in the Federal Land Policy and Management Act of 1976, which sets forth that the public lands, those owned by the federal government, remain under the stewardship of the federal government, and that although these lands belong ultimately to the American people, their resources can be managed under a multi-use principle that will allow the federal government to use these lands to meet the present and future needs of the American public (43 U.S.C. § 1701, *et. seq.*). Three different sets of federal laws and regulations govern the exploration, development, and production of minerals on federal lands: (1) hard-rock (generally metallic) claims under the General Mining Law of 1872; (2) mineral leasing under the Mineral Leasing Act of 1920; and (3) the minerals disposal system under the Mineral Materials Act of 1947.

The primary federal law governing minerals on federal lands is the Mining Law of 1872 (30 U.S.C. § 22–54). The Mining Law provides citizens in the United States with the opportunity to explore for, discover, and purchase certain valuable mineral deposits on those federal lands that remain open for the purpose of mining. The Mining Law also contains provisions that provide for the enactment of state laws that are consistent with federal law. As a result, most states have enacted laws that prescribe the manner of locating and recording mining claims, tunnel sites, and mill sites on federal lands within their boundaries. There are federally

administered lands in 19 states where mining claims or sites are allowed: Alaska, Arizona, Arkansas, California, Colorado, Florida, Idaho, Louisiana, Mississippi, Montana, Nebraska, Nevada, New Mexico, North Dakota, Oregon, South Dakota, Utah, Washington, and Wyoming.

In these states, the Bureau of Land Management (BLM) of the Department of the Interior manages the surface of public lands and the Forest Service of the U.S. Department of Agriculture manages the surface of National Forest System lands. The BLM is also responsible for subsurface mining on both public lands and lands within the National Forest System.

Proposed mining activities on federal lands trigger the application of the BLM and Forest Service regulations (see 43 CFR § 3809 for the BLM's regulations and 36 CFR § 228 for the Forest Service's counterpart regulations). The BLM's regulations establish guidelines intended to ensure compliance with the federal land policy and management act prohibition against "unnecessary or undue degradation of public lands." The following sections in 43 CFR relate to and govern mining claims under the mining laws of the United States:

- 3800 Mining claims under the general mining laws
- 3810 Lands and minerals subject to location
- 3820 Areas subject to special mining laws
- 3830 Location of mining claims
- 3840 Nature and classes of mining claims
- 3850 Assessment work
- 3860 Mineral patent applications
- 3870 Adverse claims, protests, and conflicts

In addition, the 1976 National Forest Management Act provides the statutory framework for lands within the jurisdiction of the Forest Service. The regulations are contained in 36 CFR § 228 and establish guidelines intended to ensure compliance with its regulatory requirement to "minimize adverse environmental impacts on national forest subsurface resources." In addition to the regulations, mining on lands within the domain of the Forest Service is also controlled by the National Forest Management Act (16 U.S.C. 1600–1640).

In addition to the BLM and Forest Service regulations, NEPA is a broad statutory scheme that requires evaluation of certain environmental issues with regard to mining proposals on private as well as federal lands. Any anticipated actions or operations, including mining activity, on federal lands that are expected to have a significant impact on the environment require under NEPA that an environmental impact study be performed. After the study is conducted, the results are issued in an environmental impact statement (EIS). Depending on the results of the EIS, an entity planning such activity may be required to enact measures to prevent destruction or harm to the environment. For small operations on federal lands, NEPA allows the use of an environmental assessment (EA) as a preliminary study in lieu of the EIS. The EA is intended to assist the relevant federal land management agency or agencies in determining whether environmental impacts will be significant and, if so, whether a full EIS will be required.

REMEDIATION OF CONTAMINATED SITES

The evolution of the application of the Comprehensive Environmental Response, Compensation and Liability Act (CERCLA or Superfund) to mining waste did not have the long and drawn-out course as did the history of the application of RCRA to such waste. When it was enacted in 1980, CERCLA was designed to address the growing problem of inactive hazardous waste sites throughout the United

States. CERCLA authorizes EPA to respond to the release of "hazardous substances" that may present "an imminent and substantial danger to the public health or welfare." The term *hazardous substances* is defined by CERCLA to mean

"(A) any substance designated pursuant to § 1321(b)(2)(A) of Title 33; (B) any element, compound, mixture, solution, or substance designated pursuant to § 9602 of this Title; (C) any hazardous waste having the characteristics identified under or listed pursuant to § 3001 of the Solid Waste Disposal Act (but not including any waste the regulation of which under the Solid Waste Disposal Act has been suspended by act of Congress); (D) any toxic pollutant listed under § 1317(a) of Title 33; (E) any hazardous air pollutant listed under § 112 of the Clean Air Act; and (F) any imminently hazardous chemical substance or mixture with respect to which the Administrator has taken action pursuant to § 2606 of Title 15. The term does not include petroleum, including crude oil or any fraction thereof which is not otherwise specifically listed or designated as a hazardous substance under subparagraphs (A) through (F) of this paragraph. ..."

A superficial reading of the definition of hazardous substance, particularly subsection (C), may lead one to believe that those mining wastes excluded from regulation under RCRA are likewise excluded from regulation under CERCLA by virtue of the language of subsection (C) of the definition of hazardous waste that excludes any waste the regulation of which under RCRA has been suspended by Congress. As previously discussed, the current regulatory scheme under RCRA excludes certain types of mining waste, specifically extraction and beneficiation waste, although certain smelting wastes are specifically regulated by virtue of the specific waste being listed.

Notwithstanding the attractiveness of this interpretation, such is not the current state of the law. This issue came to a relatively quick resolution when a number of parties, including mining companies, sued EPA when it put their facilities on the National Priorities List (NPL) of releases or threatened releases throughout the United States (*Eagle-Picher Industries, Inc. v. EPA*, 759 F.2d 922 (D.C. Cir. 1985)). The NPL is the list of national priorities among the known releases or threatened releases of hazardous substances, pollutants, or contaminants throughout the United States and its territories. The NPL is intended primarily to guide the EPA in determining which sites warrant further investigation and possibly remedial action.

The plaintiffs relied on the basic wording of subsection (C) of the definition of hazardous waste in arguing that mining waste was not excluded from regulation under RCRA by Congress, at least until the study discussed in the RCRA section cited was completed, and thus mining waste should be excluded from regulation under CERCLA. The court concluded the plaintiffs' position was incorrect and ruled in favor of EPA on the following rationale. The plaintiffs were correct, in the narrow sense, with regard to the argument that subsection (C) was meant to exclude from regulation under CERCLA those same wastes that were excluded from regulation under RCRA. The court, however, concluded that the exception set forth in subsection (C) does not prevent a waste from being labeled as a hazardous substance if it falls within another subsection of the definition of hazardous waste.

Accordingly, although extraction and beneficiation mining waste and certain smelting waste are not subject to regulation under RCRA and therefore are not captured in the definition of hazardous waste by virtue of its subsection (C) exclusion, if constituents of

those wastes contained elements that otherwise meet CERCLA's definition of hazardous waste, then those wastes will be considered to be a hazardous substance under CERCLA. The RCRA/CERCLA dichotomy treatment of mining waste seems to be a quirk in the law; the reader must recognize that RCRA and CERCLA serve two similar although distinct purposes. RCRA is designed to regulate the generation, storage, and ultimate disposal of wastes and to ensure in doing so that those wastes do not pose a danger to the public health. By virtue of the high-volume and low-hazard nature of mining wastes, it was determined by Congress and EPA that these wastes do not pose a danger to the public health and therefore do not warrant regulation by EPA. CERCLA, on the other hand, regulates certain specific substances that are deemed to be hazardous by their very nature, and, as such, if these substances are found in any waste, be it mining or otherwise, an "imminent and substantial danger to the public health or welfare is deemed to exist." Mining waste can be analogized to the disposal of water down the drain in residential houses: when an individual drains a bathtub of water, that waste is not regulated by CERCLA; however, if gasoline is mixed with the bath water, which is ultimately drained down the sewer, that waste is regulated by virtue of the gasoline being the constituent of the bath water.

Apart from the requirements previously discussed, CERCLA Sections 102 and 103 require operators to report discharges of hazardous materials into the environment in quantities that exceed "reportable quantities" established in EPA regulations (see 40 CFR Part 302). Further, the Superfund Amendments and Reauthorization Act of 1986 (SARA) included a new statute now commonly known as the Emergency Planning and Community Right-to-Know Act (EPCRA), which imposes additional requirements for reporting of listed toxic chemicals stored on site, spills of such chemicals, and related emergency response procedures. The EPA regulations implementing these requirements are codified at 40 CFR Parts 355, 370, and 372.

NATIONAL ENVIRONMENTAL POLICY ACT

NEPA requires federal agencies to

"include in every recommendation or report on proposals for legislation and other major federal actions significantly affecting the quality of the human environment, a detailed statement by the responsible official on—

- the environmental impact of the proposed action;
- any adverse environmental effects which cannot be avoided should the proposal be implemented;
- alternatives to the proposed action;
- the relationship between local short-term uses of man's environment and maintenance and enhancement of long-term productivity; and
- any irreversible and irretrievable commitments of resources which would be involved in the proposed action should it be implemented" (42 U.S.C. § 4332).

Before taking the action, the responsible official must consult with various affected federal, state, and local governmental representatives, and public review and comment is required. NEPA review often is used to delay or prevent significant industrial or other development.

A NEPA review is required for all "major federal actions" that "significantly affect the environment." This includes mineral leases on federal lands, actions involving expenditure of federal funds, and issuance of many types of federal permits, though most environmental permits are excluded from NEPA review. NEPA review is required for dredge or fill permits under Section 404 of the CWA

and for new source permits under the act. It is not required for air quality permits, or for any permits issued by states (though many states now have their own state NEPA laws).

The White House Council on Environmental Quality (CEQ) has issued the primary set of regulations implementing NEPA, which are codified in 40 CFR Part 1500 *et. seq.* Most federal agencies have adopted complementary NEPA regulations, which include "categorical exclusions" of agency actions for which NEPA review is not required. If NEPA review is required, the first step generally is preparation of an EA, which is designed to determine whether an action might cause significant environmental impacts that should be reviewed in more detail. If so, an EIS is required. Preparing an EIS today is usually an extremely complex task that requires at least a year or more, and EAs are becoming more detailed as well. Agency-specific NEPA regulations often will specify classes or types of agency actions for which an EIS is presumed to be required.

If a completed EA or EIS predicts no significant impacts, the lead agency will issue a "finding of no significant impact" (FONSI), and the project will proceed. If significant impacts are predicted, NEPA does not expressly require mitigation, but the CEQ regulations require the EIS to state whether all practicable means to avoid or minimize environmental harm from the alternative selected have been adopted, and if not, why not (40 CFR 1505.2(c)). If mitigation measures are adopted, a monitoring and enforcement program is required (40 CFR 1505.2(c)). Some agency regulations, such as those of the Federal Highway Administration, independently require mitigation measures for impacts identified in NEPA analyses (23 CFR 771.105(d)). Even where no such mitigation provision is involved, the social and political leverage provided by NEPA analyses often is enough to delay or prevent controversial projects.

TOXIC SUBSTANCES CONTROL ACT

The Toxic Substances Control Act (TSCA, 15 U.S.C. § 2601 *et. seq.*) is a comprehensive program for regulation of toxic materials in products. It is aimed at "chemical substances," which are defined in Section 3 to include, with some exceptions, "any organic or inorganic substance of a particular molecular identity, including any combination of substances occurring in whole or in part as a result of a chemical reaction or occurring in nature." EPA is given a wide array of tools to regulate chemical substances that may pose "unreasonable risk of injury to health or the environment." These include authority to require product testing (Section 4), regulate new products and new uses of existing products (Section 5), ban or otherwise regulate existing products (Section 6), and address imminent hazards (Section 7). Section 8 includes a variety of reporting requirements, including a requirement to inform EPA whenever new information (e.g., scientific studies) becomes available suggesting that a product may pose an unreasonable risk. Under TSCA Section 11, in an appropriate case EPA can use TSCA as a conduit to regulation under other statutes administered by the agency or, in cases involving occupational exposures, to OSHA or MSHA. EPA's TSCA regulations are codified at 40 CFR Part 700 *et. seq.*

TSCA was intended primarily to regulate the chemical industry and has rarely been used in the context of mining or mineral processing. EPA's asbestos and polychlorinated biphenyl (PCB) regulations are issued under TSCA, though the asbestos ban was invalidated by a federal court. In practice, the "unreasonable risk" standard for TSCA regulation is not as stringent as the standards for issuing similar environmental regulations (e.g., ambient air quality standards) because it requires balancing the potential risks against the benefits of the product and requires EPA to adopt the least burdensome effective regulatory alternative. Early in the process, EPA attempted to regulate lead concentrate and other lead products

under TSCA, but that did not result in significant regulation of mining or mineral processing operations. Similar attempts have been made over the years with respect to asbestos and other toxic materials in ores or concentrates but have generally not come to fruition. Efforts to regulate products containing industrial minerals have occasionally produced meaningful results. For example, in the early 1990s, EPA considered several types of TSCA regulation for refractory ceramic fibers, but the industry was able to avoid additional regulation by adopting acceptable measures in a voluntary product stewardship program.

Currently, it appears that the primary TSCA concern for operators of industrial mineral mining or processing facilities is compliance with any applicable reporting requirements for their products. Compliance with the PCB regulations is also an occasional concern. Whether the future may hold additional regulation of industrial mineral products under TSCA remains to be seen.

FUTURE OUTLOOK AND TRENDS

At the time of this writing, operators of industrial minerals facilities are facing several significant public health regulatory issues. EPA is in the process of revising the ambient air quality standards for PM, and is considering replacing the PM₁₀ standards with new coarse PM standards that would regulate the fraction PM_(10-2.5). The most recent drafts of the agency's PM Criteria Document and Staff Paper (unpublished) contain the strongest findings to date that coarse crustal PM is not likely to be harmful. EPA, however, is considering recommending coarse PM standards that are significantly more stringent than the current PM₁₀ standards and may adopt more stringent standards for fine particles as well.

Fibers in mineral particulate or products are another regulatory concern that crosses over several agency jurisdictions. So-called nonasbestiform minerals, which are essentially nonfibrous forms of asbestos, are now being investigated for further regulation, as are microscopic structures in ores and minerals that have not previously been classified as fibrous. EPA is investigating these issues under the TSCA and Superfund programs, and OSHA and MSHA are investigating them in the occupational exposure context. Similar investigations are underway with respect to crystalline silica, though they are largely confined at present to occupational exposure scenarios. Many independent companies and trade associations have begun work on comprehensive product stewardship programs designed to address these issues voluntarily in advance of additional regulatory measures.

Other "hot" issues include the establishment of TMDLs and related permit limitations under the CWA, the ability of EPA and the Army Corps of Engineers to require water permits for isolated intrastate waters, and assessment of natural resource damages under Superfund. Although it does not directly affect most industrial minerals operations, the ability of interest groups to continue or expand use of the CAA conformity requirements to delay or defeat major highway projects is also a matter of serious concern.

Sustainable Development and Industrial Minerals

Deborah J. Shields, Slavko V. Šolar, and William H. Langer

INTRODUCTION

The President's Council on Sustainable Development (PCSD) envisioned a sustainable America that would offer a dignified, peaceful, and equitable existence for all Americans (PCSD 1996). It would have a growing economy but also protect the environment, natural resources, and natural systems. The council acknowledged that economic prosperity necessitates the use of natural resources; the issue of minerals in a sustainable America, however, was never directly raised. Although the council did not explicitly exclude minerals from the national discussion of sustainability, the reality is that many individuals define resource sustainability narrowly as sustaining renewable resources—forests, grasslands, ecosystems, species, and so forth. From this perspective, the goal of sustainable resource management is to sustain resource stocks and ecosystem functioning over the long term by controlling anthropogenic impacts such as emissions and regulating harvests of timber, forage, fish, and wildlife.

Clearly, it is inappropriate to speak of mineral resources as being sustainable in the same way as are ecosystems or biological resources. Mining does, however, impact the environment. Together these facts have led many people to express the simplistic view that mining is inconsistent with sustainability (once extracted, the resource is “gone”), anathema (primarily a source of pollutants and environmental degradation), or of secondary importance (merely a source of virgin materials for which recycled materials or renewable resources can be substituted).

One source of this misunderstanding is the use of the terms *sustainability* and *sustainable development* interchangeably. Sustainability is an inherent characteristic of healthy social and environmental systems. It is achieved by maintaining or enhancing various system capacities (such as family structure and community institutions in social systems or energy flows and carbon cycling in environmental systems) so that the system can withstand external shocks and return to normal functioning. It depends on healthy, functioning social, institutional, and economic relationships in human systems and on ongoing, natural, regenerative processes in biological systems. Mineral deposition is a natural, physical process, sometimes an ongoing one, but not one that is based on short-term biophysical interconnections or system dynamics. Defined in this way, sustainability is not a characteristic of most of the earth's resource systems, which can lead people to think that minerals are not part of a sustainable future.

Conversely, mineral resources are unquestionably part of sustainable development, a commitment to which necessitates integrating

environmental policies and development strategies so as to satisfy current and future human needs, improve the quality of life, and protect the environment. Essentially, sustainable development involves managing resources in a way that is conducive to long-term wealth creation and the maintenance of capital (natural, social, human, economic, and physical). This perspective extends naturally to mineral resources, which are themselves a form of endowed, natural wealth and are an important source of monetary wealth creation (Shields and Šolar 2000). These resources are vital to human well-being. They are integral components of economic systems; the driving force for some local, regional, and national economies; the basis of the built environment; and the material embodiment of our cultural history. The mineral sector is an integral part of developed, modern societies, and a sustainable future is unachievable without its services. Mining and mineral use will continue.

Societal priorities influence how industrial companies behave (i.e., business must be conducted within the legal and ethical frameworks and limits set by society). Because the business situation and societal requirements change over time, both the costs the company must cover and the constraints on their actions change as well. How companies respond to societal expectations must make good business sense. Companies have an obligation to their shareholders and employees to achieve legitimate corporate goals such as profitability and growth. They cannot manage based on philanthropic principles alone (WBCSD 2000).

Beginning in late 1980s, the influence of the sustainable development paradigm on societal thinking began to spread, in part because its overarching goals are widely acceptable and understandable across cultures. These goals—economic prosperity, environmental health, and social equity—have influenced the public's expectations with respect to all industrial sectors, including mining. Although concern about environmental protection has been increasing ever since the emergence of the environmental movement in the 1960s, its importance has been magnified as sustainable development concepts have spread. The fundamental environmental sustainability goal is to protect natural systems (terrestrial and aquatic) that support life on Earth. The negative impacts of products and production are to be minimized. To this, sustainability has added an additional social imperative to minimize negative impacts of economic activities on employees, consumers, suppliers, the local community, and other stakeholders. There is also pressure to distribute the benefits and the costs of economic activities fairly across all affected stakeholders.

These changes have been gradual and progressive, and responding to them requires much more time and attention from the company than previously was the case. The reality is that industrial companies no longer exist as isolated islands, if they ever did. Businesses are now seen as part of society and are expected to behave responsibly toward the environment and reach out to the community.

This is clearly the case for the minerals industry. In many locations the mining sector has lost the trust of people with whom it must deal every day. In the worst-case scenarios, mining companies have failed to convince governments, lenders, shareholders, and stakeholders that they can be trusted or deserve a social license to operate. This has led to revised expectations of the industry, which the Mining Minerals and Sustainable Development project (IIED and WBCSD 2002, p. xiv) cataloged:

- “Countries [and communities] expect that minerals development will be an engine of sustained growth.
- Local communities expect that the industry will provide employment, infrastructure, and other benefits that counter the risks and impacts they will experience and will leave them better off than when the project started.
- The industry’s employees expect safer and healthier working conditions, a better community life, and consideration when their employment ends.
- Local citizens and human rights campaigners expect companies to respect and support basic human rights, even when they are operating where government does not.
- Environmental organizations expect a much higher standard of performance and that the industry will avoid ecologically and culturally sensitive areas.
- Investors expect higher returns and have shown considerable concern about the industry’s financial results.
- Consumers expect safe products produced in a manner that meets acceptable environmental and social standards.”

What does this mean for the industrial minerals sector? How will companies be affected? The bottom line is that there is a new business reality. Having a legal license to operate is no longer adequate because that, by itself, will not guarantee the existence of a social license to operate. The latter is an upgrade of the former and is granted by society, not the government. To gain a social license to operate, minerals companies must interact with a broader set of constituents than was the case in the past. In addition to legal authorities, shareholders, and lenders, the company’s management must now respond proactively to the concerns of employees, the local community, and other stakeholders. Further, the company must integrate social and environmental concerns in their operations and in their interactions with all their stakeholders (i.e., they must practice corporate social responsibility) (European Commission 2001).

The links between corporate social responsibility and profitability are becoming increasingly clear (WBCSD 2001; Sustainability, the International Finance Corporation, and the Ethos Institute 2002). In the absence of a social license, the company will face opposition to its presence as well as legal, and possibly even physical, attempts to disrupt, temporarily block, or terminate legitimate business activities. Moreover, financial institutions are insisting that companies implement sustainable practices, including gaining prior consent from impacted communities for their presence and operations (World Bank 2003). Financing options are becoming more limited for those companies who refuse to do so, with the result that their cost of capital increases, negatively affecting profitability and potentially even the economic feasibility of mine development. Inevitably, a company’s long-term viability is

undermined if it is unable or unwilling to adapt to a changing business environment, one part of which is responding to societal expectations.

This chapter presents basic sustainability principles and describes in more detail how they apply to the mining industry. It also draws a distinction between sustainability performance and a sustainable industry. The concept of sustainable industrial mineral resources management is introduced, a process for implementing the practices in the mining company is set forth, and major themes that are part of the minerals sustainability dialogue are briefly described.

PRINCIPLES OF SUSTAINABLE DEVELOPMENT

Sustainable development, according to a common definition, strives to improve the economy, environment, and quality of life for the current generation without compromising the ability of future generations to meet their needs. The foundation of sustainable development is reconciliation of a society’s development goals with Earth’s environmental limits (NRC 1999). The world’s nations have agreed on the need to transition to a sustainable development path, first at the Earth Summit held in Rio de Janeiro, Brazil, in 1992 (United Nations 1992) and again in 2002 at the World Summit on Sustainable Development held in Johannesburg, South Africa (United Nations 2003).

One reason the sustainable development paradigm has been so widely embraced is that it explicitly recognizes the interconnectedness of social, economic, and environmental systems (Moldan and Billharz 1997; Funtowicz and Ravetz 2001). Because of the holistic nature of sustainable development, many authors recommend a systems approach for such studies (Meadows et al. 1972; Allen, Tainter, and Hoekstra 2003). Erikson, Loucks, and Strafford (1999) describe three principles of systems thinking that are relevant in this context:

- Systems thinking is applicable in situations where groups of interdependent and interacting parts are linked by exchanges of energy, matter, capital, values, and information.
- A system is healthy and sustainable when variables are resilient (i.e., they can accept externally imposed stress or intervention and return to characteristic levels or patterns).
- Boundaries of sustainable systems should allow measurement of stocks and flows among the components of subsystems, identifying externalities and feedbacks and determining whether cycles and loops are open or closed.

Gunderson and Hollings (2002) argue that systems exhibit endless cycles of growth, adaptation, restructuring, and renewal, and define sustainability as the capacity to create, test, and maintain adaptive capability. This description can be applied to the minerals industry just as it can to social and biological systems; to be sustainable, companies need to adapt, restructure, and renew. At its core, the goal of sustainable development is to foster adaptive capabilities that ensure survival.

Liverman and colleagues (1988, p. 133) offer a more comprehensive description of the goals of sustainable development, one that is also consistent with systems thinking: “the indefinite survival of the human species (with a quality of life beyond mere biological survival) through the maintenance of basic life support systems (air, water, land, biota) and the existence of infrastructure and institutions which distribute and protect the components of these systems.”

This general statement leads to a variety of different, and in some cases even conflicting, understandings of sustainable development (Shields 1998). A lack of agreement notwithstanding, certain basic principles underlie virtually all definitions of sustainable development (Shields and Šolar 2004).

General sustainability principles are as follows:

- Sustainability should seek the appropriate integration of political, social, economic, biophysical, and ecological factors.
- The spatial and temporal scales of decision making, management, and regulation should be compatible with the physical, ecological, and socioeconomic scales of activities in question and their impacts.
- Adaptive management, relying on an iterative process of timely and transparent feedback from socioeconomic, resource, and ecological monitoring, is essential.

Social and economic sustainability principles are as follows:

- Progress toward sustainability should generate direct economic value as well as noneconomic values, which may be intrinsic, recreational, or aesthetic.
- Decisions and actions must be equitable and just, both intra- and intergenerationally.
- Members of the public, particularly local communities, should be empowered to participate fully in decisions that will affect their lives and the lives of their descendants.
- Information relevant to decision making should be made available to all who may be affected so that they can participate effectively.
- Governance, both governmental and corporate, must be honest, open, and fair.
- Individuals should take responsibility for the environmental and social impacts of their personal consumption and behavioral choices.

Environmental sustainability principles are as follows:

- Sustainability depends on conserving ecosystem structure and function in order to maintain ecosystem services needed for both humans and the ecosystems that provide them.
- Ecological sustainability depends on maintaining biological diversity and adequate populations of target species for long-term viability.
- Users of natural resources must recognize that there are limits and boundaries of natural resource consumption beyond which ecosystem behavior might change in unanticipated ways.
- Polluters should be responsible for environmental remediation, reclamation, and aftercare.
- Decisions on environmental protection should not be delayed, even in the absence of full information, if doing so will seriously endanger the structure and function of ecosystems.

The next section discusses in more detail how these principles can be applied in the context of mineral resources in general and minerals companies in particular.

SUSTAINABLE DEVELOPMENT AND MINERALS

There is considerable disagreement as to how minerals should be treated in the sustainable development paradigm. Conflicting views reflect the reality that value orientation affects priorities. One individual's values might lead him or her to place more emphasis on environmental protection (a biocentric viewpoint), whereas another's values might lead to greater emphasis on the benefits of extraction (an anthropocentric viewpoint). Extreme proponents of the former perspective seek to ban mining; extreme proponents of the latter demand the right to mine anywhere they choose, in any manner that they deem most profitable. Sensible sustainable development takes a middle road, acknowledging the need for resource extraction, use, and disposal, while insisting on environmental and social protections.

Not surprisingly, initial discussions about minerals and sustainable development focused on the need for a steady supply of minerals, the consequences of resource depletion, and the need for environmental protection (NASCER 1996; NRC 1999). Some authors then turned to the issue of mineral development as a source of wealth creation and, by extension, the use of mineral extraction as a tool for the eradication of poverty (Auty and Mikesell 1998; Auty 2003). A different perspective has focused on the environmental and social consequences of mineral development, use, and disposal and argues that the achieving environmental sustainability will necessitate significant reduction in the per capita use of materials (Spaargaren 2000; Bartelmus 2002).

More recent work has extended the basic principles of sustainability to mineral resources in a comprehensive manner (Shields and Solar 2000; World Bank 2003). For example, the Mining Minerals and Sustainable Development project created a set of sustainability principles relevant to the minerals situation, a subset of which follows (IIED and WBCSD 2002):

- Maximize rents to ensure efficient use of resources.
- Ensure a fair distribution of risks, costs, and benefits.
- Replace depleted natural resources with other forms of capital so as to ensure that future generations are not deprived of the benefits of current extraction.
- Promote responsible stewardship of natural resources and the environment, including remediation of past damage.
- Minimize waste and environmental damage along the whole supply chain.
- Price commodities, products, and services at levels that reflect the full cost of their provision.
- Maintain and enhance conditions for a viable enterprise.

The preceding discussion focuses on the role of the minerals sector in a sustainable future. The principles in these bullets are phrased as actions that need to be taken by government, society, or industry. Each will inevitably affect the mining company—how it does business, its profitability, and its long-term viability. Each is complex and multifaceted and can be interpreted differently by different stakeholders. For example, there is less than universal agreement as to what fair distribution means. Similarly, responsible stewardship can legitimately be interpreted in multiple ways. A full discussion of the ramifications of each is beyond the scope of this chapter. The last two principles, however, deserve further comment.

First, mineral commodities are sold in competitive markets and prices are set in those markets, not by any governmental authority. Current market prices for most, if not all, mineral commodities do not cover the full, long-term environmental and social costs of their provision (IIED and WBCSD 2002), but no individual company can rectify that situation. At a minimum, it will require an industry-wide commitment to full cost accounting and in some instances advances in national and corporate governance. Second, a viable minerals sector is essential to a sustainable future. Sustainable behaviors are undertaken by profitable companies, seldom by marginal companies or those losing money. It is in society's best interests to ensure the existence of institutional and market conditions that enable companies to stay in business and make profits adequate to enable them to both provide mineral resources and embrace sustainable performance.

SUSTAINABLE INDUSTRIAL MINERALS RESOURCE MANAGEMENT

The goal of sustainable industrial minerals resource management is not to sustain a single deposit or mine but rather to sustain the flow of benefits and services from those resources in such a way that

their contribution to society over the life cycle is net positive (IIED 2002; Shields and Šolar 2005).

Each of the primary stakeholders—government, industry, the public, and nongovernmental organizations (NGOs)—must accept certain responsibilities, and they must cooperate at the regional and local planning levels (Langer, Giusti, and Barelli 2003). The government provides the climate for success through its policies, regulatory framework, and economic incentives. The industry must work to be recognized as a responsible corporate and environmental member of the community. The public and the NGOs need to become informed about mineral resource management issues. All stakeholders have the responsibility to constructively contribute to a decision-making process that addresses not only their own but also a wide range of objectives and interests.

The U.S. government, along with many state, province, or territorial governments in Canada and Australia and many of the federal governments within the European Union and elsewhere, have national minerals policies that recognize minerals and mining as key sectors contributing to jobs, wealth, and a high quality of life for its citizens. Governments have a variety of tools that they can use to encourage sustainability, including laws, policies, guidelines, and incentives. Many countries, including the United States, have enacted laws at different levels (e.g., national, state, regional, provincial, municipal) to protect water, air, endangered species, and other aspects of the environment. These laws are an integral part of sustainability.

Some industrial minerals companies in the United States have begun implementing sustainability concepts without waiting for government intervention. These include companies that produce abrasives (Imerys), aggregates (Aggregate Industries, Lafarge, Vulcan), cement (Cemex, Holcim, Lafarge), clay (Imerys), gypsum (U.S. Gypsum), industrial sands (Fairmount Minerals), phosphate (Agrum), and talc (Luzenac)—all of whom post their annual sustainability reports or policy statements on company Web pages.

At the level of the company, key tenets commonly include that (1) the industry must strive to be recognized as a responsible corporate citizen and member of the community; (2) resource development must meet the needs of the community as well as those of the company; and (3) all stakeholders must be offered the opportunity to have a voice in decisions that will affect them and to participate in the sustainable resource management process (Langer and Tucker 2003; United Nations 2003).

Sustainable industrial mineral resources management commonly is iterative and adaptive, but it does not require than any specific process be followed. Successful management can be achieved in a practical sense by adopting some simple principles (after Plant and Haslam 1999):

- The government should strive to minimize social and environmental impacts by forward-looking planning that protects important resources from urban encroachment and protects growing communities from the nuisance impacts of poorly designed, poorly located, and poorly managed mineral operations.
- Industry should strive to minimize social and environmental impacts by using best practice designs and operations to control the effects of blasting, noise, dust, sediment erosion, and visual scarring in extractive and transport operations, and by providing for conservation of natural values by management of buffer areas that maintain or enhance vegetation and wildlife habitats and corridors.
- Industry, as enabled by governmental permitting decisions, should strive to maximize the economic value of the resource—by extracting as much material as possible from the area that

has to be disturbed, by using it for the most economically valuable use it can accommodate, and by finding uses and markets for all the material disturbed (e.g., turning crusher fines into “manufactured sand,” thus taking the pressure of natural sand sources in more environmentally sensitive areas).

- Industry should strive to maximize rehabilitation of disturbed areas by considering reclamation as part of the quarry/pit design process before extraction begins, by starting rehabilitation from day one, and by being flexible to allow advances in technology and for changing local needs.
- Industry should strive to maximize community engagement—by involving the local community in planning activities through open visit days and community awareness and educational activities. This may lead to a measure of community acceptance and a “social license to operate,” which can be just as important as the official, legal permits.

Langer and Tucker (2003) transformed the tenets of community involvement into a set of operational concepts for the social dimension of mining operations. Their work has been generalized here:

- Establish community relationships: It is never too early for a company to get involved in the community in which they do business, want to do business, or hope to stay in business. In today's world it is through the permission of neighbors that industrial minerals companies are able to continue doing business. Company strategies for each of their principal markets need to include continued community involvement by key employees. Those key employees also need to assist other employees in developing and maintaining long-term community relationships.
- Obtain executive support: The company president, his or her management team, and other appropriate managers must support the implementation of sustainability principles. Develop a sustainable business plan with input from both operations and management. Schedule team meetings regularly so that team members can exchange information and keep each other up to date.
- Create benefits for the community: Understand how your operation fits into the larger community plan and offer the community compensating, long-term advantages.
- Communicate: Identify the tools you will use to communicate the business plan, such as videos, computer presentations, pamphlets, and field trips to the site. Be open; share as much information as possible. Make sure that your message to every community group, elected official, and business leader is consistent. Keep elected officials informed, but also identify the real decision makers; sometimes they are different from the obvious ones. Know who influences the decision makers and why they have the influence.
- Solicit feedback from the community: Listen actively, take notes, ask questions, and show true interest in the communication. Make every effort to work in harmony with those of opposite views. Try to view your operation through the eyes of your stakeholders, and analyze and address their issues and concerns.
- Be visible and accessible: Be available beyond just normal business hours, Monday through Friday. Maintaining availability requires commitment of team members' personal time outside normal business hours, on a regular basis, over the term of this project proposal.
- Maintain your public trust: Remain active in the community over the life of the operation and during aftercare.

These actions are not without cost, and there remains among some in management positions the view that engaging and responding to the community represents an effort that has no added value (Galea 2004). More generally, there is considerable discussion within industry and in academic literature about the relationship between sustainability performance and business competitiveness (Porter 1991; Wagner and Wehrmeyer 2002; Ziegler, Rennings, and Schröder 2002). The traditionalist view draws a parallel between the effects of sustainability performance on the company and the effects of environmental regulation. It is argued that environmental regulation is intended to correct for negative externalities and market failures and in so doing forces companies to absorb additional costs. Companies facing higher production costs because of environmental compliance are seen as having a competitive disadvantage compared with the companies that do not face those same regulatory burdens.

There is, however, a revisionist view of environmental regulation as a policy instrument that drives innovations, which in turn lead to competitive advantage (Porter and van der Linde 1995). The analogy with sustainability is clear. The more traditional view sees additional activities focused on the range of sustainability issues as a drain on corporate profits. Alternatively, the actions can be seen as increasing the company's competitiveness, name recognition, access to markets and capital, and desirability as an employer and neighbor (Wagner and Schaltegger 2004).

SUSTAINABLE DEVELOPMENT THEMES

The literature on sustainable development is vast, and reporting on all the concepts contained therein is beyond the scope of this chapter. Rather, several important themes are described that recur in discussions of sustainable development and minerals. Four are core concepts that play out similarly across all commodities: corporate social responsibility, transparency, best practices, and risk assessment.

Corporate Social Responsibility

Corporate social responsibility (CSR) is a form of business behavior that leads companies to voluntarily contribute to a better society and a cleaner environment. Businesses take on commitments beyond common regulatory and conventional requirements, which they would have to respect in any case (European Commission 2001). The goal of CSR is to raise standards of social development, environmental protection, and respect of fundamental rights by embracing open governance, reconciling the interests of stakeholders, and taking an overall approach to quality. CSR requires company owners (shareholders) and management to act more responsibly toward employees in areas of working conditions, health, and safety, but also with regard to professional development (education), health insurance, and retirement funds. The rights and obligations of local communities, NGOs (mostly environmental), and other traditionally external stakeholders are recognized and respected.

The definition of CSR is context dependent and varies for companies in different economic situations. CSR is an interactive process among management, worker representatives, workers, public authorities, and others that requires commitment, trust, and accountability (European Commission 2001). Organizations need standards by which levels of performance can be measured (e.g., auditable standards).

Corporate culture is the very basis for corporate social responsibility. Corporate culture is determined by written, and in particular unwritten, rules that have great impact on the behavior of each company employee. The company's management sets the framework for corporate culture through corporate governance. Corporate governance is essentially about business leadership in

efficiency, responsibility, and probity. Current calls for higher standards in corporate governance have grown out of public displeasure with corporate scandals (Galea 2004) and debates about several key questions (Corporate Social Responsibility Forum 2000):

1. To whom are companies accountable—shareholders or stakeholders?
2. For what are companies responsible—financial performance or performance more broadly defined?
3. Where are companies accountable—in their home country or everywhere they operate?
4. Who sets company standards—the company, government, business associations, or NGOs?
5. Who monitors the company and what should be disclosed—self-monitoring with only legally required disclosure or external monitoring and full disclosure?

Companies that have embraced CSR, and that are implementing sustainable practices, define themselves as accountable to stakeholders, responsible for social and environmental as well as financial performance, accountable everywhere they do business, and open to external codes of conduct. Such companies institutionalize sustainability at all levels of the organization, putting clear behavioral standards and operational goals in place for field supervisors, middle managers, and upper-level managers to make clear that the commitment to CSR is real (WBCSD 2000; Dunnett 2004). They are also willing to adopt codes of conduct aimed at influencing the practices of their suppliers in both developed and developing countries by providing them with a baseline of expected standards. These are typically based on international labor standards regarding child labor, wages and benefits, working hours, disciplinary practices, the right to freedom of association, health and safety, and environmental practices (Mamic 2004).

Companies implement and promote their CSR strategies for very pragmatic reasons. Doing so is good business. It can increase long-term business viability, including growth and profits, and it sends a signal to stakeholders that the company is a good and responsible corporate citizen.

Transparency

One of the core concepts of CSR, and sustainable development in general, is information flow. The government, the financial sector, shareholders, communities, and other stakeholders need information about proposed or existing mineral operations to ensure both sound decision making and effective engagement in negotiations. In the past, however, companies shared information either because they were legally compelled to do so (i.e., compliance with environmental reporting and financial disclosure requirement) or because doing so supported core business goals (e.g., enhancing profitability, maintaining reputation, or managing risk). Achieving these latter goals in the future is going to entail a much greater degree of openness than was deemed necessary in the past.

Historically, information flow has not been equal to all stakeholders. As Thomson and Joyce observed in a presentation at the Monitoring Science and Technology Symposium (Denver, Colorado, 2004), "Information flows from companies to regulators and shareholders and trickles to all other stakeholders." This reality, combined with the legacy of past mining practices and attempts to cover up problems (successful cover-ups are unknown to the public), has led to public mistrust of mining companies. Now the industry is being asked to be more transparent (IIED and WBCSD 2002). Paragraph 46 of the *Report of the World Summit on Sustainable Development* (United Nations 2003) addresses mining and specifically calls for the promotion of transparency and accountability.

And, increasingly, stakeholders are asserting their right to information about business actions that have the potential to affect their lives and the environment.

Deeply rooted mistrust between environmental NGOs, local communities, and other stakeholders on one side and industry (and sometimes regional or national governments) on the other side can be overcome through transparency of intents and actions—from both sides. Industry has rightfully pointed out that they are sometimes held to higher standards than their critics; both corporations and their critics must meet the same standards of honesty and disclosure (IIED and WBCSD 2002).

There are many ways to increase transparency if the will to do so exists. Guidance is available from Transparency International (<http://www.transparency.org/>) in the United Kingdom, a global NGO dealing with transparency in industry, including the extractive sector. More mining oriented is the multistakeholders' Extractive Industry Transparency Initiative (EITI; <http://www.eitransparency.org/index.htm>) launched in 2002 after the World Summit on Sustainable Development. It aims to increase transparency in transactions between governments and companies within extractive industries. The EITI Secretariat is based in the United Kingdom's Department for International Development.

The core element of transparency is providing access to information. Information flow can increase understanding of the state of the world and, in the process, facilitate an iterative process of learning in the face of uncertainty and change (Bass and Dalal-Clayton 2001). The information provided should be relevant to the questions at hand and meaningful to the intended audiences. Sometimes that means sharing raw data, but raw data are seldom meaningful to the general public, decision makers, or other stakeholders. Rather, meaning emerges through analysis. In many instances it is the analyzed data that need to be shared with stakeholders. In some instances, however, indicators are needed. Effective indicators turn vast amounts of analyzed data into meaningful and relevant information that reduces complexity and brings clarity. Indicators display or predict the state of a given system or phenomenon. More important, indicators have significance extending beyond that directly associated with the measured property or properties (DETR 1997).

Some companies have developed their own sets of indicators for reporting to their publics and stakeholders. Others are using the reporting process developed by the Global Reporting Initiative (GRI 2004b). The GRI is an independent, multistakeholder process that is developing and sharing sustainability reporting guidelines for many industrial sectors, including minerals. They have created the final draft *Mining and Metals Sector Supplement* (GRI 2004a) and are developing technical protocols for indicator measurement.

The "Seven Questions to Sustainability" process offers another approach to reporting (IIED 2002). The seven questions are intended to assess the contribution of mining and mineral activities over the life cycle of the operation. The questions involve (1) public engagement; (2) human well-being; (3) environmental protection; (4) economic viability; (5) traditional and nonmarket activities; (6) institutional arrangements and governance; and (7) synthesis and continuous learning. The process was used successfully to review the Area Structure Plan that was created in response to conflict over development of an aggregate deposit in Alberta, Canada (Richards and Peel 2003).

Information sharing can also be part of best practice and certification processes.

Best Practice

One of the ways mining companies demonstrate CSR is by adopting best practice as part of their overall business strategy. Best practice

is often thought of narrowly as the process through which companies implement the most appropriate and technically effective solutions to engineering and environmental problems. Standards, handbooks, guidelines, and voluntary codes of conduct exist for every aspect of the mine life cycle, published by organizations as diverse as the United Nations Environment Programme (UNEP), the United Nations Economic and Social Commission, the World Bank, the U.S. Environmental Protection Agency, various industry associations, professional groups, and NGOs, among others. Many have been collected and categorized at the United Nations Conference on Trade and Development (UNCTAD) Mineral Resources Forum web site (<http://www.natural-resources.org/minerals/csr/practices.htm>).

Widely applied environmental standards have been built on the Berlin II Guidelines (UNEP 2002a,):

- Recognize environmental management as a high priority.
- Establish environmental accountability.
- Encourage employees at all levels to recognize their responsibility for environmental management.
- Adopt environmentally sound technologies.
- Adopt risk analysis and risk management.

Accountability in this context means both giving an account of what has happened and being responsible for one's actions (Gray, Owen, and Adams 1996). It often involves external verification of the company's activities (Epps and Solomon 2000). Increasingly, companies in the mining sector are seeking certification from the International Organization for Standardization (ISO) that they have complied with a voluntary international standard for environmental management called ISO 14000 (ISO 2005). This standard is primarily concerned with what the organization does to minimize harmful effects on the environment caused by its activities and how it will continually improve its environmental performance. The ISO also has a standard for quality, ISO 9000, that addresses what the organization does to enhance customer satisfaction by meeting customer and applicable regulatory requirements and how it will continually improve its performance in this regard (ISO 2005).

In 2004, the ISO published its *2005–2010 Strategic Plan* (ISO 2004). Their organizational vision is to facilitate trade; improve quality, safety, security, environmental and consumer protection, and the rational use of resources; and disseminate good practices. They lay out seven key objectives, which explicitly include stakeholder involvement. The stated purpose of this plan is to ensure that the ISO contributes to the achievement of a sustainable world economy. It reflects the fact that the original environmental focus of best practice has broadened in recent years to encompass all aspects of resource projects. This is exemplified by the following sustainability-based principles of best practice (Environment Australia and UNEP 2002):

- Ecologically sustainable development
- Intra- and intergenerational equity
- Accountability and compliance with international human rights and environmental standards and principles
- The precautionary principle
- Well-informed and -trained staff
- Effective communication and openness
- Flexibility
- Continual improvement

The last two principles are included in recognition of the fact that circumstances differ from mine to mine, technology advances over time, and sustainable practices require learning and adaptation.

Companies are also looking into certification of their products, or business processes and practices, as “sustainable.” In the former case, this would mean that the product has been produced or manufactured according to some agreed-on sustainable best practice, and uses inputs that were themselves produced in the same manner. In the latter case, the operation itself would be certified as using sustainable best practice. This trend toward certification has progressed rapidly in forestry, and certification bodies exist for forests themselves and for wood products (the web site of the Forest Certification Resource Center compares certification methods; <http://www.certifiedwood.org/search-modules/CompareCertSystems.asp>).

Voluntary certification is beginning to take hold in the mineral sector as well. Mining companies see this as a potential tool for “branding” an otherwise fungible commodity and also differentiating themselves from competitors who do not behave responsibly. Whereas seeking and maintaining such certification could be costly and time consuming, it could also give the company a competitive advantage. One recent example is the International Cyanide Management Code, intended to control cyanide use in gold mining (UNEP 2002b). Mines would be certified as compliant with the code by the International Cyanide Management Institute. Another example is the Mining Certification Evaluation Project (MCEP), which is evaluating the potential for a third-party certification program for the mining industry (Rae, Rouse, and Solomon 2002). The MCEP is a joint exercise among the mining industry, NGOs, labor, government agencies, the financial accounting sector, and research institutions. Four tests of the protocol took place in 2004 and results will be reported in 2005 (CSIRO 2005).

Risk Assessment

The terms *risk assessment*, *risk analysis*, *risk characterization*, *risk management*, and *risk distribution* recur in discussions of sustainable development, CSR, and best practice. Risk is the possibility of an unwanted outcome in an uncertain situation. Every action in life has an associated risk: eating, travel, the type of physical activity in which one engages, how much sleep an individual gets. Each can directly influence one's life in a positive or adverse manner. It cannot be known for certain what the influence will be, though outcomes can be predicted to a greater or lesser extent depending on past experience, knowledge of circumstances, and an understanding of the consequences of alternative choices.

The same is true for mineral extraction, which by definition takes place in a location that can be only partially characterized in biophysical and socioeconomic terms. A degree of uncertainty inevitably exists about the true nature and extent of the deposit or the type and extent of adverse environmental and social impacts from mining. That being the case, companies assess risk to identify potential sources of harm to people and the environment from all aspects of their business, with the goal of determining whether sufficient precautions or preventive measures have been taken (Health and Safety Executive 1999).

Risk assessment is a multiphased process of (1) scoping and problem formulation, (2) analysis, and (3) risk characterization (EPA 2003). The first step, defining the problem to be assessed, depends on input from experts other than those who know how to do risk assessments, including persons who are knowledgeable about the potentially affected community and its values. The analysis phase is given over to the analytic process, where risk assessment experts apply science to a problem. It requires the use of rigorous, replicable methods that are evaluated under agreed-on protocols of an expert community, which results in a systematic use of information to identify hazards and to estimate the likelihood and consequences that they will be realized. Environmental risk

analysis separates risk to the environment from other mining risks such as occupational safety and health issues and risks to community stability.

Finally, risk characterization is a deliberative process that integrates and interprets the results of the analysis phase and addresses the problems formulated in the planning and scoping phase. The qualitative or quantitative risk assessment results are described; assumptions, limitations, and uncertainties are listed and associated with results; and ultimate uses of results are considered. Thus the process in its entirety uses a systematic approach to identify and evaluate potential environmental and social impacts, the consequences of those potential impacts, the likelihood that those potential impacts will happen, and ways to reduce the seriousness of those impacts.

The next step is risk management. Risk managers use the results of risk assessments, plus economic, social, and legal considerations, to make decisions (Kamrin, Katz, and Walter 1996). When implemented, monitored, and reviewed, risk management can reduce the uncertainty of the business. The goal is reduction of risk and related costs through education, regulation, and cleanup. Uncertainty is unavoidable, but keeping it within tolerable limits is very beneficial for the company performance. The “polluters pay” principle, widely accepted and legalized, states that those who pollute should pay to clean up after themselves. Failing to manage the risk of environmental damage can thus lead to the imposition of significant, unexpected costs that can heavily damage the company and may even cause bankruptcy.

Another, more complex definition of risk management was originally developed by the Presidential Commission on Risk Assessment and Risk Management (PCRRM 1996). They proposed a process that starts with risk assessment, but goes further to add making decisions, taking action, conducting ex post evaluation, and, most important, involving stakeholders in every step of the process. This approach is consistent with the principles of sustainability on public participation and transparency. It is not, however, without difficulties.

Risk means different things to different people, and there are wide variances between “experts” and the lay public. Engineers view risks as a numerical value: a function of probability and consequences. The public's understanding of risk is contextual and typically nonmathematical. An individual's subjective definition of risk may be influenced by a wide array of psychological, social, institutional, and cultural factors. The hazards and risk that are likely to be of most concern are those that pose threats to locally valued social and institutional arrangements.

Moreover, it has long been recognized that people tend to be poor risk estimators (Tversky and Kahneman 1981). They overestimate the likelihood of some accidents (motor vehicle, tornadoes, or venomous bites and stings) but underestimate the risk of other potentially dangerous events (lightning strikes, asthma attacks, or complications from diabetes) (Slovic, Lichtenstein, and Fischhoff 1979). This occurs because people assign greater probabilities to events to which they are more frequently exposed, and they judge the risk of an event based on reference to other events that they think resemble it, even if the resemblance carries little or no relevant information (Montgomery 1995). In addition, people are very averse to risks that could result in catastrophic outcomes or outcomes that they do not understand well, even if the likelihood of occurrence is very low (Montgomery 1995).

For the company, communication of risk information depends on the perceived credibility and unbiasedness of experts. If there is no trust in experts, there will be no trust in the risk estimate. What risks the public considers tolerable or acceptable depends on how

they view the data on which the risk measure is based and whose values were considered. These factors bring us back to the core debates of sustainability: Whose value system counts and who gets to judge the importance of loss?

Increasingly, communities want to see the risks (real or perceived) to which they are exposed matched by comparable benefits (IIED and WBCSD 2002). As in the case of risk alone, people base their judgments about risk/benefit relationships not only on what they think but also on what they feel (Slovic et al. 2003). "If they like the activity, they are moved toward judging the risks as low and the benefits as high; if they dislike it, they tend to judge the opposite—high risk, low benefit (Slovic et al. 2003, p. 5)." This reality complicates the situation and makes the effective communication of risk challenging for the company, but also essential.

MATERIAL TRACKING AND LIFE CYCLE ASSESSMENT

The National Research Council (NRC) report entitled *Materials Count: The Case for Material Flows Analysis*, by the Committee on Material Flows Accounting of Natural Resources, Products, and Residuals of the Committee on Earth Resources (NRC 2004), recommended that the nation develop material accounts that would track the sources, flows, and dispositions of materials (including minerals) to determine more effective strategies for improving environmental and economic performance and efficiency of resource use. These accounts would provide information to legislators and decision makers as they devise and implement policies intended to support our transition to sustainability.

Tracking flows already takes place at the company level in the form of life-cycle assessment (LCA). LCA is an objective process to evaluate the environmental burdens associated with a product, process, or activity by identifying energy and materials used and wastes released to the environment and to evaluate and implement opportunities to affect environmental improvements (Barnhouse et al. 1998). The process has four steps (UNEP and WBCSD 1996, p. 8):

1. Goal and Scope Definition, the product(s) or service(s) to be assessed are defined, a functional basis for comparison is chosen and the required level of detail is defined;
2. Inventory Analysis of extractions and emissions, the energy and raw materials used, and emissions to the atmosphere, water and land, are quantified for each process, then combined in the process flow chart and related to the functional basis;
3. Impact Assessment, the effects of the resource use and emissions generated are grouped and quantified into a limited number of impact categories which may then be weighted for importance;
4. Interpretation, the results are reported in the most informative way possible and the need and opportunities to reduce the impact of the product(s) or service(s) on the environment are systematically evaluated.

An outgrowth of LCA is the emerging concept of product stewardship, or extended product responsibility. Stewardship appears to have first been used in an environmental context by the Canadian Chemical Producers Association (CCPA) in their Responsible Care Code in the late 1970s (CCPA 2000). The term *extended producer responsibility* originated in Sweden, with the goal of decreasing environmental impacts of products by assigning responsibility for take-back, recycling, and disposal (Lindhqvist and Lindgren 1990). The PCSD (1996) identified extended product responsibility as a tool for reducing waste, conserving resources, and preventing pollution. This version of the concept is voluntary; shares responsibility among consumers, government, and industry rather than focusing exclusively on one part of the

supply chain (Lewis 2005); and, in addition, omits the postconsumer stage (Fishbein 2000).

Companies in the industrial minerals sector are beginning to embrace product stewardship. Rio Tinto Borax, for example, commits in Corporate Policy No. 410 to "the responsible and ethical management of our products from the extraction of natural resources, through design, processing, marketing, distribution, use, and disposal" (Goldberg 2004).

Another outgrowth of LCA is the shift from perceiving mining companies as mineral extraction companies to seeing them as material suppliers. The business activities of this type of company could include a mixture of extraction, trade, and recycling, and the remanufacture and processing of minerals for reuse. For example, many quarries use their processing equipment for recycling construction and demolition waste that has technical characteristics similar to the primary aggregate. Steps (voluntary or legislated) intended to increase the percentage of recycled materials support this trend (HM Customs and Excise 2004).

CONCLUDING REMARKS

To ensure the sustainability of mineral resources, each of the primary stakeholders—government, industry, the public, and NGOs—must accept certain responsibilities:

- The government is responsible for developing the policies, regulatory framework, and economic climate that provide conditions for success.
- The industry must work to be recognized as a responsible corporate and environmental member of the community with a social license to operate.
- The public and NGOs have the responsibility to become informed about natural resource management issues and to constructively contribute to a decision-making process that addresses not only their own but also a wide range of objectives and interests.
- All stakeholders have the responsibility to identify and resolve legitimate concerns, and the government, industry, and the public must cooperate at regional and local levels in planning for sustainable minerals extraction.

Sustainable minerals resource management would be less difficult if all conflicts between regional minerals resource needs and local impacts had solutions that would leave everyone better off. This is seldom the case, and there are usually winners and losers. But as the amount of accessible land that is underlain with suitable industrial minerals resources diminishes, inequalities increase. The longer that implementation of sustainable resource management principles is delayed, the more difficult it will become.

PART TWO

Commodities

Abrasives

Gretchen K. Hoffman

INTRODUCTION

Abrasives are substances, both natural and synthetic, used to grind, polish, abrade, scour, clean, or otherwise remove solid material, usually by rubbing action (as in a grinding wheel) but also by impact (pressure blasting). Facts about the discovery, early use, adaptation, and development of abrasives before the 20th century are few. From the sparse, earliest information that is available, it appears that the science of abrasives began when, to fashion tools, humans selected certain rocks over others because of their useful properties. There is evidence that some sort of grinding machine sawed stones as early as 4000 BC in Egypt. The real expansion of abrasives use coincided with the beginning of metallurgy in the Middle East around 2000 BC. The earliest confirmed use of abrasives for grinding metal comes from a steel dagger found along with a sharpening stone that dated to 1500 BC.

Natural and manufactured abrasive substances play an important role in fashioning and finishing numerous products with a wide variety of applications. The mining and preparation of crude, natural abrasives for market and the manufacture of synthetic and other abrasive materials contribute significantly to the U.S. economy (Table 1). Just as sawing to specific dimensions enhanced the value of Egyptian stone, the use of abrasives in the fabrication of modern products and the addition of abrasives to others add value. The following discussion draws heavily from Hight (1983) and Wellborn (1994).

GENERAL CONSIDERATIONS

The most important physical properties of materials that qualify as abrasives are hardness, toughness (or rigidity), grain shape and size, character of fracture (or cleavage), and purity (or uniformity). To fabricate bonded abrasive products such as grinding wheels, additional considerations include stability under high heat and bonding characteristics of grain surfaces. The economic factors of cost and availability are always important.

No one singular property is paramount for any use. Some applications require extreme hardness and toughness, as in diamonds for drill bits. For other uses, factors of greatest importance are hardness, the ability to break down slowly and, in the process, develop fresh cutting edges when grains become worn. In garnet sandpaper, for example, highly cleavable, friable, or extremely tough grains are not desirable. For other uses, extreme hardness may be objectionable, such as abrasives for dentifrices and for glass-

Table 1. Salient U.S. abrasives statistics

Natural Abrasives Production	1999	2000	2001	2002	2003

cleaning soaps. For efficiency uses in critical applications, different types of abrasives rarely can be completely interchangeable. Although both crushed quartz and garnet are used in sandpaper, the two abrasives are not interchangeable in their applications.

In the final analysis, the choice of a high-grade abrasive depends on the quality and quantity of work performed by the abrasive per unit of cost. Initial cost of an artificial abrasive may be much greater than that of a natural abrasive, but the artificial mineral may do better work faster, so the ultimate cost is less. For this reason artificial abrasives have largely replaced natural abrasives.

Abrasive Value

Mineralogical hardness, or “scratch” hardness, as expressed in Mohs scale is an important property in evaluating abrasive materials, but it

Table 2. Relative hardness of abrasive materials on the Knoop scale

Substance	Knoop Hardness (K100)
Quartz	820
Garnet	1360

is only one of several essential properties. The mineral hardness of pure crystal almandine garnet is about 7.5. The useful hardness may be much lower if incipient fracture planes cross the crystal, or if it contains inclusions of other minerals. Although the quartz grains in sandstone have a hardness of 7, the bond holding the grains together may be so weak that the stone is valueless as a commercial abrasive. The hardness, strength, and character of the bond in artificially bonded wheels and stones are fully as important as the hardness of the abrasive grains. For abrasive hardness of loose grains, both scratch hardness and toughness must be considered. In natural or artificially bonded abrasive stones, the character of the bond is of equal, if not greater, importance.

The problem of abrasive hardness is further complicated by the shortcomings of methods for testing hardness and expressing relative values. The Mohs scale is inadequate because the methods of testing are very crude and the intervals between steps in the scale are not uniform. There is far less difference between a hardness of 6 and 7 on the scale than between 9 and 10. Numerous attempts have been made to remedy these deficiencies. Knoop, Peters, and Emerson (1939) devised a diamond indentation method of measuring hardness that gives reproducible results on a wide variety of materials and definite numerical values over a wide range, up to diamond hardness, that is still currently used. Table 2 lists Knoop hardness values of various abrasive materials. Other methods of testing hardness are Vickers and Rockwell. The Vickers indenter is shaped like a square pyramid, whereas the Knoop diamond is an elongated pyramid shape; the Rockwell test uses a diamond cone or hardened steel-ball indenter.

Toughness or friability are perhaps more important than true hardness in appraising abrasive value. Very hard materials are necessarily neither tough nor resistant to fracture. Diamond is the hardest material known, yet it fractures easily under impact. Several techniques for testing friability are in widespread use in the quality control of abrasive grains. The basic operating principle common to all strength-of-grain tests is to impact a given sample of abrasive grain under a set of standardized conditions and then measure the amount of breakdown. The higher the survival rate, the tougher the grain, other factors held constant.

A simple and inexpensive device for testing friability is an ordinary ball mill. The standard *Ball Mill Test for Friability of Abrasive Grain* outlines this test (ANSI 1987).

Grain shape is another fundamental physical property that must be considered in selecting the best abrasive for a particular application. Blocky and nearly equidimensional grains are identified as strong-shaped and are less friable than slivery or flakey grains, which are considered weak-shaped. In grinding wheels, strong-shaped grains are preferred in extra-heavy-duty applications involving high heat and pressure, and weak-shaped grains are selected for precision grinding to close tolerances and where highly polished surfaces are required.

Close control of abrasive shape is necessary in modern abrasive technology. The bulk density of an abrasive is a dependable indicator of shape, because bulk density is a function of shape. A sample of weak-shaped grains will not pack as efficiently and will have a lower bulk density than the same abrasive with a strong shape.

Various techniques are used to measure the bulk density (shape) of abrasive grain. The loose-pack density test is described in ANSI B74.4-1992 (R2002), *Procedure for Bulk Density of Abrasive Grain* (ANSI 1992). In performing this test, care must be taken to avoid vibration. The container is filled to overflowing and then carefully leveled with a straight edge. The grain filling the container is weighed and the bulk density calculated using the conventional formula:

$$D = W/V,$$

where D = bulk density of the sample, in g/cm³

W = weight of the grain, in g

V = volume of the cylinder, in cm³.

Characteristics other than shape also influence the strength of abrasive grains. The manufacture and processing of aluminous abrasives permit control of some of these important characteristics. For example, laboratory and field tests have clearly established that the finer the crystal size of an abrasive the stronger that abrasive will be. The cooling history of a fused alumina melt is the dominant factor influencing the crystal size of the finished product. Generally, rapid cooling will result in finer crystals (400 µm) and slow cooling will produce coarser crystals (3,000 µm).

A rapid and inexpensive quality control check for crystal size is the monocrystalline count. Any convenient grit size can be used, but 24-grit is ideal. A petrographic microscope can reveal whether a grain consists of a single crystal (monocrystalline) or two or more crystals (polycrystalline). A count is made of 100 grains and the percentage found to be monocrystalline is the monocrystalline count. The higher the monocrystalline count, the weaker the grain. A polycrystalline grain is less apt to disintegrate because a fracture passing through one crystal in the grain is deflected on encountering another crystal not in crystallographic continuity with the first.

Heat treatment or roasting strengthens fused aluminum oxide abrasive grain. The heated slag (impurities between crystals) softens and flows on to the surface of the grain, cementing imperfections and sealing incipient fractures.

TYPES OF ABRASIVE PRODUCTS

Loose Abrasive Grains

Abrasive grains are produced from a wide variety of materials for use as grains and for incorporation into other products. Abrasive grains are important products and are the starting point for making bonded shapes, coated abrasives, abrasive tools, polishes, cleaners, grinding pastes, and other compounds. Garnet, flint, and chert are used for pressure-blasting silica sand and other natural mineral

grains such as corundum. Manufactured grains such as fused alumina, silicon carbide, and steel shot are also employed. Each use has its own special requirements. All grains except steel shot have a Mohs hardness of 7 or more. Besides hardness, the physical properties of toughness, grain shape, grain size, uniformity, and specific gravity are important. Grains should be tough so that they will not disintegrate readily under impact. For some uses, rounded grains are considered desirable. For others, sharp cutting edges are favored. Uniformity of grain size and other physical properties are always desirable. The higher the specific gravity, the greater the force of impact for grains of equal size.

Pressure blasting is used to clean stone and concrete, clean metal castings, prepare surfaces for painting, and etch glass and plastics. Relatively coarse grain sizes are used for sawing stone, rough grinding plate glass, and surfacing stone. Quartz sand, garnet, corundum, emery, aluminum oxide, and silicon carbide are common materials used. Slag abrasives dominate the blast cleaning market in Europe (Labrakis, An dronikos, and Kaliampakos 2002). Recently, sodium bicarbonate has been used as an alternative to silica sand for cleaning, buffing, degreasing, polishing, and coating removal. It is biodegradable, water soluble, and safe for most surfaces.

Smaller abrasive grains are used for grinding lenses, rough-polishing gems and ornamental stones, and dressing and polishing wood surfaces.

Fine-grained powders are specified for polishing and lapping glass, tile and artificial stone flooring, gems, semiprecious stones, and wood surfaces. Fine abrasives are rouge, crocus, tin oxide, aluminum oxide, chromium oxide, cerium oxide, diamond dust, feldspar, garnet, rottenstone, pumice, diatomite, tripoli, ground silica, clay, whiting, and zirconium oxide. Most automobile body cleaners and polishes contain diatomite. A familiar bathroom and kitchen scouring powder for glass and porcelain items contains feldspar or pumice. One method of drilling small holes in glass, porcelain, gemstones, and similar materials uses a brass tube. It is charged with diamond, corundum, emery, aluminum oxide, silicon carbide, or boron carbide dust in a water, oil, or grease carrier. Diamond-tipped drills are also used for this purpose.

Emery, magnetite, silicon carbide, and aluminum oxide are cast into the treads of steps and ramps to increase traction.

Bonded Abrasives

Abrasive grains, closely sized, are bonded and pressed or molded into a wide variety of bonded abrasives such as grinding wheels, honing stones, and tumbling media. The abrasives in such products were originally corundum or emery. The use of natural abrasives has declined greatly with the introduction of electric-furnace abrasives (aluminum oxide and silicon carbide).

Five main types of bonded abrasives, depending on the type of bond and method of manufacture, are as follows:

1. Vitrified wheels with a clay-feldspar bond that is made in ceramic kilns. Because of their high rigidity and dimensional stability, vitrified bonded wheels are preferred for precision grinding operations. They are unaffected by water, acids, oils, and ordinary temperature variations.
2. Resinoid wheels with a hard synthetic resin bond. These are high-speed wheels used in foundries and in welding shops, and for billet conditioning. They are also used in cutoff and thread-grinding operations.
3. Rubber wheels, bonded with natural or synthetic rubber. These are somewhat elastic in nature. They are used for grinding ball races, most centerless feed wheels, and for portable snagging operations where finish is an important

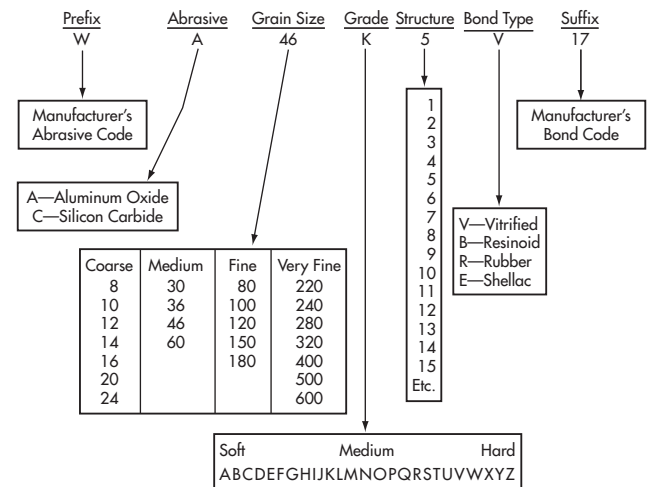

Figure 1. Wheel-marking system used in the abrasives industry

consideration. Rubber-bonded cutoff wheels can be made very thin.

4. Shellac wheels used for producing high finishes on items such as camshafts and paper mill rolls.
5. Silicate bonds for applications where heat generated in grinding must be kept to a minimum. Silicate bonded wheels are mild acting and are used in grinding-edge tools of all kinds.

Wheels vary in at least five physical properties aside from size and shape:

1. Type of abrasive grain (aluminum oxide, silicon carbide, diamond, etc.)
2. Grit (size of abrasive grains ranging from 8 to 1,500 mesh)
3. Grade (strength of bond encompassing 18 to 20 grades)
4. Structure (grains with 10 to 12 spacings)
5. Bond (vitrified, etc., in five bond types)

Figure 1 shows a wheel-marking system that is widely used in the abrasives industry.

When all these variables are combined with an almost infinite number of sizes, shapes, and spindle diameters that are either standard or available on special order, the complexity of the abrasive wheel business becomes apparent.

In addition to grinding wheels, bonded abrasives are made into blocks, bricks, and sticks; used as sharpening and polishing stones (oil stones or scythestones); and as razor and cylinder hones. Curved blocks and segments can be combined into large wheels such as pulpstones, or used mounted or unmounted for grinding or polishing the interior or exterior of curved surfaces.

Structured abrasives consist of fine abrasive grains mixed uniformly with a binder and shaped using microreplication techniques to form small geometrically shaped protrusions on a flexible backing. A 0.33-mm mineral height allows a continuous fresh supply of sharp minerals. Rubber pencil and ink erasers contain abrasive grains, and similar soft rubber wheels, sticks, and other forms are made for finishing soft metals.

Coated Abrasives

Coated abrasives consist of sized abrasive grains cemented to a paper, woven cloth, polyester film, or vulcanized fiber backing.

Sandpaper was originally coated with silica sand, but today crushed quartz is used on silic a-type paper because its grains have much sharper cutting edges. The principal abrasives used for this purpose are aluminum oxide, silicon carbide, alumina–zirconia, Sol-Gel alumina, crushed quartz, and garnet. Most emery cloth is now coated with silicon carbide or aluminum oxide. Flint paper in the United States is coated with crushed quartz, but true flint is used in Europe.

With the exception of sintered abrasives, all abrasive grains, natural or artificial, are made by graded crushing and close sizing. Crushing usually is done in two rolls to a void extreme fines—for which there is little demand—with close screening between. Products are passed through magnetic separators to remove iron-bearing material abraded from the rolls, and again precisely sized on screens. Careful sizing is essential to prevent contamination of grain grades. The finest powders are sized by air or water flotation and sedimentation.

In earlier practice, grade numbers were more or less arbitrarily assigned to grain sizes and garnet, flint, and emery scales were all different. Artificial abrasives were given numbers based on screen mesh designations now specified in ANSI B74.18 (ANSI 1996). Several grit grain-sizing standards exist worldwide. In Europe, the Federation of European Producers of Abrasives (FEPA) and International Organization for Standardization (ISO) are recognized. In Japan and Asia, the Japanese Industrial Standard (JIS) is recognized. Table 3 shows the relationship between the scales.

The bond for coated abrasives can be either glue or a synthetic resin. An initial coating—the *make coat*—of resin or glue is applied to the backing, and the grain is then electrocoated onto the surface. This electrostatic process ensures uniform distribution and optimum positioning of the grains. A second coating—the *size coat*—of resin locks the particles into place on the backing. The bonded material is cured and processed into various belts, rolls, discs, or wheels. Garnet and flint papers and cloths are most widely used for wood, leather, hard rubber, plastics, felt, and rubbed paint and varnish finishes on metals. Cloth, coated with silicon carbide, is used chiefly in the metal working industries. Alumina–zirconia and Sol-Gel abrasives are finding increasing use in heavy-duty cloth belts for industrial purposes.

Grains and Powders for Soap, Cleaners, and Polishes

Many different materials—mostly natural, but some manufactured—are used in making soaps, cleaners, and polishes. Feldspar, pumice and pumicite, sand, ground quartz, tripoli, diatomaceous earth, clay, and wood flour are ingredients in hand and scouring soaps. Low price is often the primary factor in the selection of the abrasive. Occasionally, the abrasive is an important factor in the formulation and use of a product. A household cleanser should contain neither quartz nor any mineral of hardness equal to or greater than that of glass or enamels, nearly all about a Mohs hardness of 6 or lower. Otherwise, the glass or enamel surface would be readily scratched. Such cleansers should not contain calcium carbonate, calcium sulfate, or other easily reactive lime compounds because lime reacts with most soaps to form insoluble substances that are difficult to remove from glass or enamel surfaces.

An ideal mineral abrasive for soaps, cleaners, and polishes would be a mineral or rock between 3 and 5 in hardness, occurring in abundance in easily mined deposits, close to rail transportation, and within a reasonable freight-haul distance of important markets. The material should be uniform in texture and physical properties.

The ultimate grain size of abrasives in this group depends on the finished product. Sizes range from extremely fine, air-separated and water-floated particles with sizes expressed in micrometers

Table 3. Size grades for abrasives*

Industrial U.S. Mesh	Micrometer Grade	FEPA or P-Grade†	JIS Grade

* Blanks indicate that there is no equivalent size in that particular sizing system.

† P series is used only in micrograins. FEPA has an F series whose equivalents in micrometers are different.

(much finer than 325 mesh) up to 100 mesh or even coarser for heavy-duty scouring soaps.

CLASSIFICATION

Abrasives can be divided into two general classes, natural and manufactured. The former includes all rocks and minerals used for abrasive purposes without chemical or physical change other than crushing, shaping, or bonding into suitable forms. Manufactured or artificial abrasives are made by either heat or chemical action from metals or mineral raw materials. Table 4 lists most of the important abrasives, classified by inherent type and the forms in which they are used industrially.

Manufactured products can be substituted for most natural products, usually at higher initial cost but with greater efficiency. This is not always the case. For example, there is no satisfactorily manufactured garnet substitute for making coated abrasive paper and cloth. For some abrasives such as chaser stones and others with declining use, the production of manufactured substitutes has not been economically attractive. For a low-priced commodity such as pressure-blasting steel shot, fused aluminum oxide and silicon carbide may be substituted.

The use of many natural abrasives such as sand and quartz has seriously declined because of government regulation of free crystalline silica (a carcinogen). The siliceous abrasives have been replaced with manufactured abrasives. The transition has not been a net loss to the mineral industry because virtually all manufactured abrasives are made from mineral raw materials.

Natural Abrasives

This book devotes separate chapters to such commodities as diamonds, diatomite, tripoli, pumice and pumicite, silica sand, and quartz. Thus, this chapter discusses these rocks and minerals only as abrasives.

Table 4. Classification of abrasives

Natural Abrasives						
Superior Hardness (>7.0 on Mohs scale)	Intermediate Hardness (H 5.5 to 7.0)		Inferior Hardness (H < 5.5)	Manufactured Abrasives		Types of Abrasive Products
	Silica Abrasives	Other Rocks and Minerals				
Diamond 10.0	Buhrstone	Argillaceous limestone	Apatite	Boron carbide	Lampblack	Abrasive grains and powders, loose
Corundum 9.0	Chalcedony	Basalt	Calcite	Boron nitride	Lime	Abrasive grains bonded into wheels, blocks, and special shapes
Emery 7.0 to 9.0	Chert	Feldspar	Chalk	Calcium carbonate (pptd*)	Magnesia (pptd)	Coated abrasives; grains bonded to paper and cloth
Garnet 6.5 to 7.5	Flint	Granite	Clay	Calcium phosphate	Manganese dioxide	Abrasive grains and powders; paste form; oil or water vehicles
Staurolite 7.0 to 7.5	Novaculite	Mica schist	Diatomite	Cerium oxide	Periclase (artificial)	Abrasive grains and powders; brick and stick form; grease, glue, and wax binders
	Quartz	Perlite	Dolomite	Chromium oxide	Silicon carbide	Natural rocks shaped into grindstones, pulpstones, chaser stones, millstones, etc.
	Quartzite	Pumice and pumicite	Iron oxides	Clay (hard burned)	Tantalum carbide	Natural rocks shaped into sharpening stones such as oil stones, whetstones, scythestones, razor hones, etc.
	Sandstone	Quartz conglomerate	Limestone	Diamond	Tin oxide	Natural stones shaped into rubbing and polishing stones such as holystones and pumice scouring blocks
	Silica sand		Rottenstone	Fused alumina	Titanium carbide	Natural stones shaped into blocks for tube-mill and pebble-mill liners
			Siliceous shale	Glass	Tungsten carbide	Pebbles, natural and manufactured, for grinding mills
			Silt	Iron oxides	Zirconium oxide	
			Talc		Zirconium silicate	
			Tripoli	Metallic abrasives, including steel wool, steel shot, angular steel grit, brass wool, and copper wool		
			Whiting	Porcelain blocks for mill liners and grinding pebbles		

Adapted from Wellborn 1994.

* pptd = precipitated.

Corundum and Emery

Corundum and emery have become relatively unimportant. Most of the emery is used as hardener for heavy-duty concrete floors and as nonskid material on bridges and at tollbooths. The competition from synthetic abrasives eliminated most of the markets for the se materials; only niche markets remain (Harben 2002). There is some limited use of the material as tumbling media.

Production. No corundum is currently mined in the United States or Canada. No production or imports of emery or corundum are reported for the United States. Turkey, the largest producer, reported 14.5 Mt of emery in 2003 (Mobbs 2003) and Greece produced an estimated 8 Mt (Newman 2003).

Diamonds—Industrial

The United States has no production of natural diamonds and is therefore dependent on imports.

Natural Industrial Diamonds. The four major types of natural industrial diamonds are as follows:

1. Bort, which includes off-color, flawed, or broken fragments of diamonds unsuitable for gems
2. Carbonado or black diamond, which is a very hard and an extremely tough aggregate of very small diamond crystals
3. Ballas, a very hard, tough, globular mass of diamond crystals radiating from a common center
4. Diamond crystals used for grinding wheel dressing

Carbonadoes come only from Bahia, Brazil. Ballas comes chiefly from Brazil, but some is from South Africa. Bort comes from all diamond-producing centers. There is a considerable production of diamond dust and powder waste from cutting gem diamonds. Several new diamond operations have opened in the Northwest Territories of Canada and exploration continues. In 2003, Canada produced about 15% of the world's diamond production (Olson 2003b).

Uses. The industrial diamond has become one of the most important and essential materials in modern industry. Diamond drilling, once used only for locating metallic ores, is now widely used for exploring geologic structures for oil and gas; testing foundations of dams, buildings, and heavy machinery; exploring the internal condition in heavy concrete structures such as dams, step mining, and explosive demolitions under special conditions; and for miscellaneous other purposes.

Some of the most important uses are as follows:

- Diamond drill bits for drilling rock and concrete
- Diamond dies for wire drawings
- Diamond-tipped tools for truing abrasive wheels and for turning and boring hard rubber, fiber, vulcanite, hard plastics, and so forth.
- Diamond-toothed (segmented) saws and rim-impregnated (continuous rim) saws for sawing stone, glass, quartz, and metals, and for slicing expansion joints in concrete highways, etc.

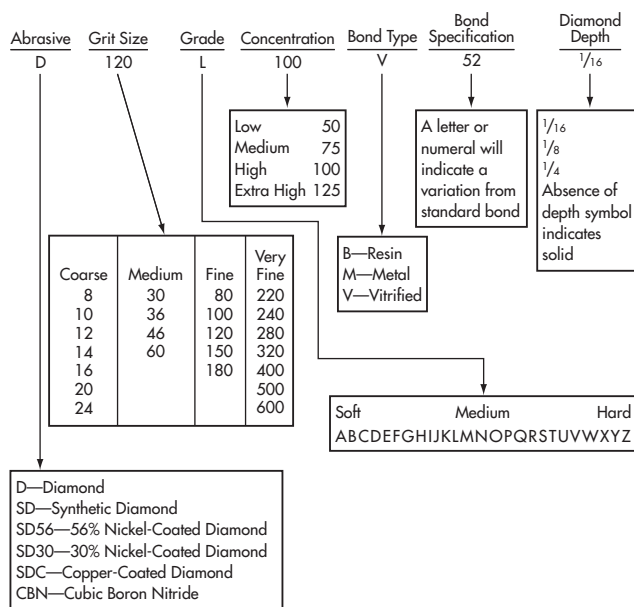

Figure 2. A diamond wheel-marking system

- Abrasive wheels, both for grinding and cutoff work in which the working face consists of diamond grit bonded with a metal or ceramic resinoid
- Diamond-tipped tools for cutting glass and for engraving gems
- Diamond powder for cutting gems

Cemented carbides and other exceedingly hard, tough alloys can be cut and shaped efficiently with diamond tools. Diamond-tipped tools are essential for the rapid and accurate shaping, truing, and dressing of abrasive wheels.

Quality Control and Testing. A diamond wheel-marking system (Figure 2), analogous to that previously shown for ordinary grinding wheels, is used by the abrasives industry. With diamond, as with ordinary abrasives such as aluminum oxide and silicon carbide, the previously mentioned properties of size, shape, and friability must be closely controlled so that diamonds with the proper physical properties can be selected for a particular application.

Resinoid or vitrified bonded diamond wheels require a fairly friable, weak-shaped, diamond abrasive grain. Metal bonded wheels require a more durable, strong-shaped grain.

A device similar to the bulk density apparatus used for ordinary abrasives is applied to diamond abrasives (Hight 1971). The cardinal rule in any determination is close reproducibility of conditions from one test to another. Another shape test is a microscopic technique developed at the Diamond Research Laboratory, Johannesburg. It is fast and inexpensive, but quite subjective. Custers and Raal (1959), who recognized four shape categories, further refined this method. Shape No. 1 is a near perfect cube or sphere whereas shape No. 4 is a thin flake or a needlelike grain. Shape Nos. 2 and 3 are intermediate. The arithmetic mean of 100 grains is calculated, and this number becomes the “shape count” for that particular sample. Belling and Dyer (1965) devised a friability test at the Diamond Research Laboratory.

Imports. The United States is the largest single consumer of industrial diamonds. It is estimated that apparent domestic consumption of both natural and synthetic industrial diamonds in 2004

was approximately 423 million carats (Olson 2005b). U.S. imports of natural diamond stones in 2004 were 2 million carats with a value of \$11.7 million (Olson 2005b). The United States was a net exporter of synthetic diamond grit and powder, and a net importer of natural industrial stones.

Garnet

The name *garnet* is given to a group of iron–aluminum silicate minerals having similar physical properties, crystal forms, and general chemical formulae.

Composition. In garnet, the general formula is $A_3B_2(SiO_4)_3$, where the *A* divalent element can be calcium (Ca), magnesium (Mg), ferrous iron (Fe^{2+}), or manganese (Mn). The *B* trivalent element includes aluminum (Al), ferric iron (Fe^{3+}), or chromium (Cr), and rarely, titanium (Ti). Further, titanium also replaces silicon in some examples. There are three prominent groups—aluminum, iron, and chromium—and various subdivisions under each, many of which blend into each other (Table 5).

Properties. Minerals of the garnet group have specific gravities that range from 3.4 to 4.3; have vitreous, resinous, or dull luster; and are transparent to opaque. Garnets have a cubic crystal system that is commonly rhombic dodecahedrons, tetragonal trisoctahedrons, or a combination of the two. They have a glassy structure and usually have a marked conchoidal fracture. Sometimes, however, the mineral tends to break into thin flakes. In some garnets the fracture is sharp and uneven. Index of refraction of the garnet group ranges from 1.735 to 1.94. Occasionally an indistinct dodecahedral cleavage is observed. Some species of almandine possess a pronounced laminated structure; the laminae are planes of weakness along which the mineral separates. This parting is not related to the crystal form and is not a true cleavage. Garnets having high iron content, such as almandine, fuse at about 1200°C. White garnets containing a considerable percentage of chromium are infusible. Aggregates of garnets are composed of individual crystals of various sizes, are brittle, and shatter readily. Massive garnet and well-formed crystals are remarkably tough and shatter with difficulty.

Occurrence. Garnet commonly occurs as an accessory mineral in a large variety of rocks, more particularly in gneisses and schists. It also occurs in contact with metamorphic deposits, crystalline limestone, pegmatites, and serpentines, and as gangue in ore veins formed at high temperatures. Most varieties of garnet are resistant to chemical and mechanical erosion and tend to be concentrated in sand of present-day or ancient beaches, streams, or other alluvial deposits.

Garnet is found in many foreign countries and in nearly every state in the United States. Large domestic resources of garnet occur in coarsely crystalline gneiss near North Creek, New York; other significant domestic resources occur in Idaho, Maine, Montana, New Hampshire, North Carolina, and Oregon (Olson 2005c).

Recent production has come from three companies, two operating in New York and one in Idaho. Montana had garnet production in 2002, but operations are now closed. Imports primarily from Australia, China, and India have displaced the domestic market.

According to data from Willis (2003) and Austin (1991), Barton Mines Corp. produces almandine garnet from an igneous–metamorphic rock of uncertain origin in Warren County, New York. It is used in sand blasting, precision powders for glass grinding and polishing, and water-jet cutting. The NYCO Division of Processed Minerals Inc., Essex County, New York, recovers and sells crude garnet concentrate, a by-product of its wollastonite operation, for additional refining and use as blasting and filtration media. Reserves in New York are large—more than

Table 5. Garnet classification

Mineral	Formula	Color	Specific Gravity	Mohs Hardness
Almandine, iron aluminum	$3\text{FeO} \cdot \text{Al}_2\text{O}_3 \cdot 3\text{SiO}_2$	Deep red, brownish red to black	4.1–4.3	7.0–7.5
Grossular, calcium aluminum	$3\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot 3\text{SiO}_2$	White, pale green, or yellow	3.4–3.6	6.5–7.0
Pyrope, magnesium aluminum	$3\text{MgO} \cdot \text{Al}_2\text{O}_3 \cdot 3\text{SiO}_2$	Deep red to black	3.5–3.8	6.5–7.5
Spessartine, manganese aluminum	$3\text{MnO} \cdot \text{Al}_2\text{O}_3 \cdot 3\text{SiO}_2$	Brown to red	3.8–4.3	7.0–7.5
Andradite, calcium iron	$3\text{CaO} \cdot \text{Fe}_2\text{O}_3 \cdot 3\text{SiO}_2$	Yellow-green, black, green	3.7–4.1	6.5–7.0
Uvarovite, calcium chromium	$3\text{CaO} \cdot \text{Cr}_2\text{O}_3 \cdot 3\text{SiO}_2$	Emerald green	3.4–3.8	6.5–7.0

Adapted from Harben 2002.

600,000 kt of high-quality garnet are recoverable from the Barton Mines' Ruby Mountain deposit. Similar deposits occur in the area (Austin 1991).

WGI Heavy Minerals Inc. has mining operations in northern Idaho at Emerald Creek, two jigging plants, and a mill in Benewah County, where garnet recovered from garnet-bearing gravels is used primarily for blasting and filtration media and water-jet cutting (Austin 1991). In March 2005, WGI was re-permitted by the U.S. Army Corps of Engineers at a current mine life of about 10 years. This will extend the reserve of garnet grades for two of their target markets, water-jet cutting and oil industries (U.S. Army of Corps of Engineers 2004).

Garnet is or has been commercially mined in Madagascar, Japan, Argentina, India, and Tanzania. Alluvial almandine garnet is mined in Western Australia (Port Gregory), and a hard-rock operation produces almandine garnet in New South Wales in Australia. In Australia, GMA Garnet of Geraldton, Washington, is the world's largest producer at more than 100 ktpy (Cullen 2004). Barton Mines Co. LLC of the United States owns the company along with Garnet International Resources based in Perth. India's garnet production is concentrated in southern India in Tamil Nadu and is primarily for export. The major producers in India are Vetri Vel Minerals Ltd. (VVM), Indian Ocean Garnet Sands Co., and Transworld Garnet India, a subsidiary of WGI Heavy Minerals (Willis 2003).

Preparation for Market. Almost 100% of the garnet sold is sized and graded. Mining techniques and end use govern sizing. Sizing generally conforms to specific standards (e.g., Standards for Quality Criteria, and Standard Methods of Test, Rating, Certification) established in cooperation with the U.S. Department of Commerce's National Institute of Standards and Technology (NIST) to provide a uniform basis for fair competition. Grading standards for coated abrasive use and micrometer sizing for grades used in glass grinding and metal lapping have exceedingly close tolerances. Wheel grades, polishing grades, and sand blast grades each have different standards and much greater tolerances. Specifications can be found in *Grading of Certain Abrasive Grain on Coated Abrasive Material* (ANSI 1996) and in *Size of Abrasive Grain-Grinding Wheels, Polishing and General Industrial Uses* (ANSI 2001). Specifications are increasingly tied to Occupational Safety and Health Administration (OSHA) regulations and certification standards set by the Coated Abrasives Manufacturers Institute (Harben 2002). In the United States, a material used as an abrasive is required to contain little or no free silica; pass the Toxic Characteristic Leaching Procedure (TCLP); conform to the U.S. military specification *Abrasive Blasting Media Hull Blast Cleaning* (Naval Sea Systems Command [Ship Systems] 1993) for the content of total metals, soluble metals, and radiation; and receive certification from California Environmental Protection Agency's Air Resources Board (Harben 2002).

Practically all garnet grains used today are heat-treated to improve adhesion rather than inherent abrasiveness. This degree of heat exposure is known as RT treatment. Impurities picked up during processing adhere to garnet particle surfaces and destroy cleanliness and capillarity needed to give adhesion for bonding. In the mid-1960s, the coated abrasives industry accepted uniform color standards for cleanliness of the grain surface and presented a color standard most closely approaching the natural red color of abrasive garnet.

There is no exact method for testing the abrasive quality of garnet or any loose abrasive except by practical application. Several rough tests and examinations indicate their abrasive possibilities. Fracture, sharpness and shape of the grain, character of the grain structure, and the presence of inclusions of other minerals, which weaken the grain structure, can be studied under the microscope. Hardness and toughness of grains can be roughly determined by placing a definite grade, such as #60, between two glass microscopic slides and rubbing them together. Skilled technicians can assess the relative scratch hardness of the grains and the amount of breakdown.

NIST developed an abrasive tester primarily for testing the abrasive quality of corundum. It can be adapted for testing the abrasive quality of any loose, abrasive grain. This type of grain is also tested on various production or laboratory machines that evaluate glass (stock) removal on flat plates. This data can be correlated with the anticipated performance of the material to be abraded as an evaluation of actual abrasive performance. In all these methods, actual stock removal is determined by either weighing or measuring. In the coated abrasives industry, test belts are made and stock removal is measured on test blocks. These tests measure stock removal only and are a valuable indicator when other important variables such as bond, backing, coating flex, and grit size are closely controlled.

In judging the abrasive quality of garnet and all other abrasives, stock removal is important but it is not the only factor to be considered. Surface finish is, in most cases, a more important factor. An abrasive used on some materials can be too hard and cause scratches so deep in the substructure that they cannot be removed in subsequent operations. If the abrasive does not have the proper grain shape or becomes dull (does not break down to yield new sharp cutting edges), it will tend to burn or gouge the material being worked.

Uses and Markets. Garnet-coated papers and cloths are used primarily for sanding wood, but also for finishing leather, hard rubber, plastics, glass, and softer metals. Coated abrasives have been improved in recent years, mainly by using resin bonds in place of glue bonds for certain applications. Electrostatic coating is now in general use. Garnet is being replaced in many of these applications by synthetic abrasives such as silicon carbide and fused alumina.

During World War II, when imported corundum became scarce for grinding optical lenses, garnet was the logical substitute

mineral. It had never been processed for this application, however. After development, garnet filled the critical need, and its desirable qualities became widely known. Its use decreased lens scratching, produced a superior finish, and, as a result, improved product quality. Using garnet reduced rejections and decreased polishing time, both important factors in the development of more economical lens grinding. The properties that made garnet a competitive abrasive for this application continue to produce new markets in the glass, plastics, ceramics, and soft metal industries. High-quality garnet powders are used for polishing and finishing cathode-ray tube (CRT) faceplates, liquid crystal display (LCD) screens, semiconductors, and polishing ceramics (Willis 2003). Abrasive powders from garnet make up 10% of the total end use in the United States.

A major nontechnical use of garnet in loose form is blasting and water-jet cutting. Garnet has the advantage of containing no free silica and thus it cannot cause silicosis. Being heavier than quartz, garnet delivers harder blows than quartz grains of equal size. Production of Idaho garnet is sold to aircraft industries on the U.S. West Coast as a blasting agent because of its price and location. Water-jet cutting requires consistent grading, good cutting speed, and durability, all of which garnet grains provide. In the United States, garnet use is primarily as blasting media (35%) and water-jet cutting (30%) (Olson 2005c).

Garnet, in different grain sizes, is also used for the manufacture of grinding wheels, as tumbling media, for nonskid applications, and as filter media. In powder sizes, it is made into lapping and buffing compounds. Water filtration is 15% of the total garnet end use in the United States.

Markets and Prices. In general, every abrasive has an application for which its qualification surpasses others, but in applications where qualifications overlap there is keen competition, based on relative cost, and grinding and finishing abilities. Garnet has maintained its position in the ever-expanding abrasives market through exploration and application of new technology. Because of health issues, garnet has the potential to increase its market share in areas previously supplied by silica sand. Market prices of garnet grains and powders vary widely, depending on garnet type (almandine, pyrope, etc.), purity, particle size, grade control, shipping quantities, and packaging.

Production. In 2004, the United States produced about 10% of the world's garnet. Reported production of crude garnet was 29.7 kt with a value of \$3.2 million. Imports into the United States were 50.4 kt of industrial garnet (Olson 2005c). Table 1 shows crude garnet production in the United States from 1999 to 2003.

Estimated world production for 2004 is 283 kt (Olson 2005c). Australia, India, and China are large producers of garnet. Production from China is on the rise, with one major producer, WuXi Ding-Long Trading-Sinogarnet. Sinogarnet's mines are in Inner Mongolia and produce almandine garnet from a biotite garnet schist containing 45% to 70% garnet (Willis 2003). Markets include Japan, Taiwan, Australia, India, Europe, Canada, the United States, the Middle East, and Africa. Uses include sandblasting, water-jet cutting, glass polishing, and textile and paper abrasives. Other operations in China have been plagued by long domestic transport distances, low quality control, and lack of water for cleaning (Willis 2003).

Staurolite

Staurolite, a complex iron-aluminum silicate, has been commercially recovered from various placer deposits in the southeastern United States, with one at a DuPont operation in Stark, Florida. Hardness—7 to 7.5 on the Mohs scale—is equal or slightly higher than that of quartz. Staurolite is used mostly for pressure blasting.

Latest production data are not disclosed, but 2002 industrial-grade staurolite production decreased 15% in quantity and 6% in value compared to 2001 (Spencer 2003).

Silica

Silica Sand. The use of silica sand as an abrasive has significantly decreased because of the potential health hazard from crystalline silica. In the United States, OSHA has created a permissible exposure limit stipulating the maximum amount of crystalline (free) silica to which workers may be exposed in an 8-hour shift. Garnet, olivine, slag, and fused alumina are being marketed as "safer" alternatives.

Abrasive sand accounted for 3% of the total amount of industrial sand and gravel sold or used in the United States in 2004 (Dolley 2005). The amount used for sandblasting in 2003 was 796 t valued at \$27.3 million with an average value of \$34.33/t. In addition, 55 t of ground sand, used in scouring powders, was sold at an average price of \$54.26/t. An undisclosed amount of silica sand used for sawing and sanding sold at an average price of \$38.25/t in 2003 (Dolley 2003).

Quartz. Crushed and graded quartz is used as the abrasive in flint sandpapers. Almost any deposit of massive white quartz is suitable. Being the cheapest of all the abrasive-coated paper, this product is still sold in fair amounts, mainly in hardware stores and by small jobbers. It is made only in the form of paper, not as cloth. True chalk flint from England and France is used extensively for this purpose in Europe; it has better cutting qualities and longer life than ordinary quartz.

Crushed and ground sand, sandstone, powdered quartz, and silt are sometimes used in hand soaps, scouring compounds, and harsher metal polishes.

Soft Siliceous Powder Abrasives. Some natural, highly siliceous materials occur as a powder or a fine abrasive used only in a powdered form as a mild abrasive. For most of these materials, use as an abrasive is of minor importance compared with their principal applications. The abrasive uses of diatomite, pumice, and tripoli are reviewed here.

Diatomite production in the United States comes primarily from California and Nevada, with small outputs from Oregon and Arizona. Abrasive uses include metal (silver) polishes, dental powders and pastes, and buffing compounds. More significant markets are filtration media, mineral fillers, and absorbents.

Included within the category of pumices are lump pumice and pumicite or volcanic dust, a natural powder. Lump pumice is used by manufacturers of furniture and musical instruments for dressing wood and metal surfaces, by silver platers for preparing metal surfaces, by lithographers for cleaning stone surfaces, by restaurants for scouring grills and cooking utensils, in household cleansers and hand cleaners, and by jeans manufacturers for stonewashing denim (Hoffer 1994). Pumice is also used for rubbing down and polishing fine tools and instruments. Pumicite or ground pumice is mainly used as a cleanser where thin, sharp, and striated grains are particularly suitable. Minor uses for abrasive pumice entail applications in polishing compounds; in polishing powders for bone, celluloid, and hard rubber; in dental use; in electronic circuit board preparation; and in the manufacture of some rubber erasers.

The fine-grained, porous materials—tripoli and rottenstone—are known to the trade as *soft silicas*. In the United States, white or cream tripoli comes from southern Illinois. Buff-to-rose-colored tripoli is mined and processed in Garland County, Arkansas (Malvern Minerals Co.), and similar material, mined in northeast Oklahoma, is milled in southwest Missouri. The colors are imparted by minor iron content. Tripoli from the Oklahoma-Missouri district

(American Tripoli Co.) is mainly used for metal finishing, for lapidary, and as friction products, including scouring agents.

Tripoli is composed of microcrystalline quartz grains that do not have distinct sharp edges and therefore perform a mild abrasive function in toothpaste, industrial soaps, and metal polishing compounds. It is employed to a small extent in the manufacture of some scouring and cleaning powders and for rubbing down painted surfaces such as automobile bodies.

Cream tripoli from southwestern Illinois is differentiated from rose tripoli based on its low iron content, high reflectance, and color, allowing for use in a wide range of filler-and-extender uses. It is also employed in buffing and polishing compounds and is in high demand for use in white coloring operations on high-class work. Chemically precipitated amorphous silicas are also used in polishing and buffing compositions.

Rottenstone, a fine-grained, gray-buff, siliceous-argillaceous limestone, comes from Antes Fort, Lycoming County, Pennsylvania, and is used as a base for automobile polishes.

Five firms in the United States produce and process tripoli (Dolley 2003); two of these companies specifically list abrasive uses for their products. American Tripoli Co. produces crude material in Ottawa County, Oklahoma, and finished material in Newton County, Missouri, which is used in metal finishing, lapidary, and friction products. Malvern Minerals Co. in Garland County, Arkansas, produces crude and finished material from novaculite primarily used as filler and extenders and as a wet-blasting media. Keystone Filler and Manufacturing Co. in Northumberland County, Pennsylvania, processed rottenstone from a fine-grained siliceous shale purchased locally (Dolley 2003).

The end use for tripoli has changed dramatically in the past 30 years because of the regulation of crystalline silica. In 1970 almost 70% of processed tripoli use was as an abrasive. In 2003 only 16% of the production was used for abrasive applications (Dolley 2003). The current primary use (70%) of tripoli is as a filler and extender in paints. The amount of processed tripoli, including amorphous silica and Pennsylvanian rottenstone, used or produced in the United States in 2003 was 68.8 kt, valued at \$17.7 million (Dolley 2003). The average reported unit value of all tripoli sold or used was \$257/t. The average reported unit value for abrasive tripoli used or sold in the United States during 2003 was \$194/t. The consumption and production of tripoli are not expected to change significantly in the future because the markets are well defined and the potential of new end uses is relatively low (Dolley 2003).

Other Soft Abrasives

Ground Feldspar. Ground feldspar is extensively used in scouring and cleaning compounds and for a window cleaner.

Chalk. Chalk (calcium carbonate) is a soft, compact, fine-grained, white limestone composed of the calcareous remains of microscopic marine shells. A small amount of this chalk, mainly from England and France and known in the trade as "whiting," is used as a very mild abrasive for hand polishing nickel, gold, silver, or plated ware, buttons, and similar materials.

China Clay. China clay (kaolin) and some pipe clays have been used successfully in polishing powders. Pipe clay at one time was the standard polish for naval and military tunic buttons.

Bath Brick. Bath brick, used for scouring steel utensils, is made from very fine-grained, quartzose clay found along the banks of the Parrot River in England.

Special Silica Stone

Although in general stones made from bonded artificial abrasive grains have largely replaced natural sharpening stones, there is still

small production of oilstones, whetstones, and deburring media in Arkansas, and whetstones and oilstones in New Hampshire. Arkansas novaculite stones are still preferred by surgeons, carvers, and engravers for sharpening fine-edged tools. It is claimed that these stones give a smoother and longer-lasting edge.

Natural abrasive stones are made from a wide variety of materials, including sandstone, novaculite, mica schist, siliceous argillite, shale, slate, and pumice. The superior cutting quality of some of these stones is due to the well-disseminated, fine-grained inclusions of garnet or other minerals of superior hardness.

Table 1 lists the quantity and value of finished grindstone, oilstone, and whetstone products sold or used by producers in the United States from 1999 to 2003 under the category "special silica stone products." Production in 2003 was 1,070 t valued at \$313,000. Arkansas accounted for most of the total quantity and value. Exports of special silica stone in 2003 were valued at \$7.8 million and categorized as hand-sharpening or polishing stones. The value of imported silica stone was \$6.3 million; a portion of the finished products imported were probably made from crude novaculite produced in the United States and exported for processing (Dolley 2003).

Grinding Pebbles and Tube-Mill Linings

Tube mills, conical mills, and cylindrical batch mills are most often used for the fine grinding of hard ores, minerals, paints, chemicals, ceramic bodies, glazes, enamels, portland cement clinker, and similar materials. Most efficient grinding can be done in mills with iron or steel liners and iron or steel balls, slugs, or rods. Where contamination of the color or chemical purity of the product by metals and metal oxides must be avoided, the grinding surfaces consist of blocks or bricks for the mill linings, and natural pebbles or artificially prepared balls are specified for grinding media. These materials should (1) have high abrasive hardness; (2) have great toughness and freedom from flaws that will result in breaking and chipping; (3) produce a white powder when abraded; and (4) contain no dark-colored metallic impurities such as iron or manganese. Although most of the natural and artificial mill linings and pebbles have a specific gravity close to that of quartz (2.6), pebbles with greater density have obvious advantages. The heavier the pebbles per unit of size, the greater the impact and abrasive grinding forces. Thus, with heavy pebbles, less mill volume is needed for a given mill capacity (throughput). With equal pebble volume, faster grinding can be done. Small balls—having more surface area per kilogram than large balls—grind faster, but with small pebbles the unit weight is low unless high-density pebbles are used.

The favored natural mill-lining material for most purposes is Belgian silex, which is a very hard, tough, more-or-less cellular quartzite resembling French buhrstone. It is imported in rectangular blocks essentially shaped to fit the curve of a mill. During World Wars I and II, when imports were cut off, and to a much lesser extent at other times, domestic substitutes have been used. These have consisted chiefly of quartzite from near Jasper, Minnesota; Iron City, Tennessee; and Baraboo, Wisconsin; and granites from Salisbury, Lillesville, and Faith, North Carolina. Some of these materials are reported to give service equal to that of Belgian silex. Special hard, dense, porcelain blocks are used in some mills for grinding paint, ceramic, and chemical materials.

For grinding media, Danish flint pebbles, when available, have long been standard because of their superior hardness, toughness, and uniformity. These pebbles are found on the shores of Greenland but are marketed through Denmark. Other foreign sources of similar pebbles exist along the seacoasts of Belgium, France (between Le Havre and St. Valéry-sur-Somme), Norway, and England. Seven sizes of Danish pebbles are marketed, ranging from 25.4 to 203 mm.

Table 6. Crude manufactured abrasives produced in the United States and Canada, by type

Type	2002	2003	2004*
Silicon carbide, kt†	30	35	35
Value, 1,000 US\$	15,900	18,500	21,500
Fused aluminum oxide, regular abrasives, kt	20	20	25
Value, 1,000 US\$	5,300	5,800	7,300
Metallic abrasives, kt‡	218	193	194
Value, 1,000 US\$	101,000	90,800	92,000
Total, kt§	268	248	254
Total value, 1,000 US\$	122,200	115,100	120,800

Adapted from Olson 2004, 2005a.

* All 2004 data are estimated.

† Approximately one half of quantity and value consists of material used for refractories and other nonabrasive purposes.

‡ Does not include reported exports.

§ Excludes U.S. and Canadian production and value of aluminum–zirconium oxide.

Domestic substitutes for grinding media are natural pebbles of flint, quartz, and quartzite, and pebbles artificially rounded by tumbling small blocks of quartzite, granite, chalcedonized rhyolite, or other siliceous materials in rotating cylinders. During World War II, natural pebbles were shipped from Encinitas Beach, California (true flint); Jasper, Minnesota (quartzite); the Austin chalk beds in south-central Texas (true flint); Salisbury and Faith, North Carolina (granite); Baraboo, Wisconsin (quartzite); and several other points in the United States. Extensive deposits of quartzite pebbles in southwestern Saskatchewan have been reported. Beach pebbles were reported to be nonuniform in hardness and required careful sorting.

Ceramic pebbles are made from very dense, tough porcelain, alumina, and sillimanite (mullite). A dense, heavy pebble having a specific gravity of 3.7 is made from zircon. For certain purposes, blocks of ore are used as grinding media. This practice has been followed to some extent in the autogenous grinding of some nepheline syenite. Ceramic products and high-alumina grinding media are tending to replace natural materials in these niche markets.

Manufactured (Artificial) Abrasives

The discovery of the electric-furnace method for making silicon carbide by Edward G. Acheson in 1891 began the revolution in the high-grade abrasives industry. Before that time, all abrasives were natural minerals and rocks except for minor chemically prepared materials such as rouge and Vienna lime. Today, artificial abrasives, with a few notable exceptions such as diamond and garnet, dominate the field of high-grade abrasives. Manufactured abrasives are essential to modern industry because they are not only superior to natural abrasives but are also uniform in quality and their properties can be varied to meet differing needs. Modern, high-speed, streamlined production methods require very accurate, specialized tools with a degree of uniformity and dependability that cannot be met with natural abrasives.

Manufactured abrasives may be divided into three main groups: (1) electric-furnace products, (2) chemical precipitates, and (3) miscellaneous additions.

Electric-Furnace Abrasives

Electric-furnace abrasives include silicon carbide, fused aluminum oxide (alumina–titania; alumina–chromium oxide; alumina–zirconia; alumina–zirconia–titania), and boron carbide.

Silicon Carbide. Silicon carbide, with the chemical formula SiC, is commonly known by the trade names Carborundum and Crystolon. It is made by fusing a mixture of high-grade silica sand and carbon in an electric furnace. The preferable form of carbon used is petroleum coke, but anthracite and coke made from coal low in ash have been used. High iron and alumina in the ash are objectionable because they tend to assist in the formation of elemental graphite and metallic silicon during the reaction. High-ash carbons make impure grades of silicon carbides.

Silicon carbide is made by charging a resistance-type electric furnace with pure glass sand and finely ground petroleum coke. The silicon of the sand combines with the carbon from the coke to form silicon carbide. The temperature at the core of the furnace is about 2,200°C. If the temperature is too high, silicon carbide decomposes: The silica is volatilized and the carbon becomes graphitized. The time of a run is about 60 hours (36 hours heating and 24 hours cooling). At the end of the run, the core consists of loosely knitted silicon carbide crystals surrounded by unreacted or partially reacted raw materials. The quality of the product depends largely on the raw materials used and the accuracy of control and operation of the furnace. Several types of products are made in which the toughness of the grains varies. A special surface treatment is given to grains for coated abrasives to increase adhesion of the glue.

The lump material from the furnace is first crushed in jaw crushers and then sequentially processed in roller, ball, or hammer mills. It is passed through a magnetic separator to remove magnetic impurities. The grains are screened mechanically into 20 or more standard sizes from 8 to 240 mesh. The finer flour sizes are prepared by air or water flotation and sedimentation.

Olson (2005a) shows crude manufactured abrasives produced in the United States and Canada during 2000 to 2004. Total production of silicon carbide in 2004 was 35 kt compared to 45 kt in 2000 (Table 6). About half the 2004 total value and quantity is material for metallurgical and other nonabrasive applications (Olson 2004). The average value of a abrasive-grade silicon carbide at the point of manufacture was estimated at \$614/t (Olson 2004). Washington Mills in Hennepin, Illinois, produced abrasive-grade and metallurgical-grade silicon carbide. The United States exports and imports crude and refined silicon carbide. Imports for consumption are estimated at 197 kt for 2004 (Olson 2005a). Imports of crude silicon carbide come from 8 countries, and 21 countries supply refined silicon carbide to the United States. China supplies 57% of the crude and 36% of the ground and refined imports (Olson 2004). The value of crude silicon carbide from China averages \$452/t; the remaining amount of crude silicon carbide imports has an average price of \$389/t. The average price of ground and refined silicon carbide imports is \$1,000/t. China has been excluded from the European Union markets because of import tariffs; therefore, China's main markets for silicon carbide are North America and Japan (Harris 2004). Other major producers are Norway, Japan, Mexico, Brazil, and Venezuela. China (455 kt) and Norway (80 kt) are the top producers of silicon carbide (Olson 2005a).

Fused Aluminum Oxide. Aluminum oxide abrasives are made in electric-arc furnaces. Bauxite, the crude raw material, should have the following typical chemical properties:

Al ₂ O ₃	85.0% to 87.0%
TiO ₂	3.0% to 4.5%
SiO ₂	3.0% to 5.5%
Fe ₂ O ₃	6.0% to 10.3%
Loss on ignition (LOI; plus combined H ₂ O)	1.0% to 2.0%

The ore as mined is crushed and then calcined to remove both free and combined water. The calcined ore (80%) is mixed with iron borings (15%) and ground coke (5%) and charged into the furnace. The coke reduces the impurities, which combine with the iron and sink to the bottom of the furnace.

At the end of the melting and reacting period, the charge is poured into cooled molds and allowed to cool under controlled conditions to obtain desired crystal size. The finished, crystallized alumina typically consists of about 96% Al_2O_3 ; 2.7% TiO_2 ; 0.67% SiO_2 ; 0.11% Fe_2O_3 ; and 0.40% other oxides. Fused aluminum oxide made with bauxite is referred to as brown fused alumina, or BFA. For certain purposes, Bayer-process alumina is used instead of calcined bauxite, making a product with >9% Al_2O_3 called white fused alumina, or WFA. White fused alumina is used entirely for grinding wheels (O'Driscoll 2003).

The cooled mass from the furnace is crushed, screened, and cleaned in about the same way as silicon carbide. Several types of grains are made that vary in toughness, type of fracture, glue adhesion, and other properties. Another form of fused Bayer-process alumina is achieved with the addition of 0.15% to 3.00% chromium oxide. Adding chromium oxide increases the hardness of these abrasives without substantially increasing the toughness. These properties are useful in preparing grinding wheels that produce a cool grind without resulting damage to the metal being ground.

Other heavy-duty fused abrasives have been developed. One is an electric-furnace fusion product made primarily of intimately crystallized mixtures of aluminum oxide and zirconia. Although other proportions have been successful, two mixtures—one containing approximately 25% and the other about 40% zirconia—have found the most widespread commercial applications in niche markets. The 25% zirconia product is used in bonded abrasive applications for foundry markets (\$1.00 to \$2.00/lb) and the 40% zirconia is used for selected bonded and coated abrasives costing \$1.50 to \$3.00/lb. Another fused abrasive is composed of a mixture of alumina, zirconia, and titania, which is fast-cooled or quenched. A favored mixture contains 34% zirconia, 3% titania, and 63% alumina. Fused alumina–zirconia abrasives have extreme durability and are particularly well suited for foundry snagging and steel conditioning.

Uses of fused aluminum oxides included bonded abrasives, coated abrasives, and closed blasting systems where the material can be recycled many times and chemical purity is important, such as in the aircraft industry (O'Driscoll 2003). Bonded and coated abrasive products account for most of the consumption of fused aluminum oxide. Fused aluminum oxide in a micropowder form is used in industrial and electronic applications that require fine surface finishing (Olson 2004).

Table 6 shows data on the production of fused alumina from 2002 to 2004. Data on production of alumina–zirconia abrasives are withheld. Estimated production in 2004 of fused aluminum oxide in the United States and Canada was 30 kt with an estimated value of \$10.7 million (Olson 2005a). Of this total, 25 kt was regular grade (valued at \$7.3 million), and 5 kt was high-purity fused aluminum oxide (valued at \$3.4 million). Imports increased from 164 kt in 2003 to an estimated 213 kt in 2004. Imports of crude fused aluminum oxide were from China, Canada, and Venezuela. Ground and refined imports were from China, Germany, Brazil, Austria, and Canada (Olson 2005a).

Boron Carbide. Boron carbide (B_4C) is an artificial abrasive introduced in 1934 by the Norton Company under the name Norbide. Although considerably harder than silicon carbide, it is far from the hardness of diamond (see Table 2). It is made from B_2O_3

and carbon in the form of petroleum coke in a carbon-resistance or arc furnace at about 2,600°C. The finished product is crushed and ground to make a range of sizes of grains and powders. In grain form, it is used for grinding and lapping operations previously possible only with diamond dust. Pulverized boron carbide can be molded under very high heat and pressure to form extremely wear-resistant products such as pressure-blast nozzle liners, thread guides, extrusion dies, and all types of extremely accurate plug, snap, and ring gages. It is not manufactured into bonded wheels or sharpening stones. Washington Mills was the only producer of boron carbide in the United States in 2004.

Sintered Abrasive

A different family of abrasives is the sintered product. This group differs drastically in method of manufacture from the more conventional fused product. The raw materials are heated in kilns only to the sintering temperature (1,200° to 1,400°C) rather than being carried all the way to the fusion point. Although other basic starting materials have been used, bauxite, with or without additives and still in the green (unfired) state, is formed into predetermined sized and shaped granules by certain granulation techniques or by extrusion through an appropriately shaped orifice. The resultant presized and preshaped granules are then sintered to make the finished abrasive grain. Process steps such as crushing, shaping, and sizing (common to manufacturing fused products) are eliminated in making a sintered product.

Sol-Gel Abrasives

Sol-Gel abrasives are prepared by jelling a form of aluminum oxide known as boehmite, adding various precursors to enhance the properties along with a seed or nucleation agent (various types have been used), evaporating the water from the gel, and producing a hard, solid material. The resulting product is crushed and graded into sizes and fired at 1,200° to 1,500°C. 3M, a diversified technology company, and Saint Gobain, who pioneered the products, hold the patents.

Although most of the raw materials used in the Sol-Gel process are considerably more expensive than those going into regular aluminum oxide abrasives, the performance of the Sol-Gel abrasives—particularly in paper, cloth, and grinding wheel applications—seems to justify the additional cost in a number of uses. In 1991, Sol-Gel abrasives were predicted to dominate the high-quality abrasives market; the market share has not materialized, however, because of high manufacturing costs (Burke 2004). The minimum pricing for Sol-Gel products is \$6 to 8/lb.

Manufactured Diamond

In February 1955, General Electric Co. announced that its laboratories had succeeded in producing diamonds from carbonaceous material subjected to pressures of about 5.5 GPa at very high temperatures for prolonged periods. Crystals up to 1.6 mm long were made in 16 hours, but smaller ones were produced in much shorter times. The pressure capable of maintaining temperatures above 2,760°C at pressures up to about 11 GPa. Costs were reported to be about twice that of comparable natural diamonds, and the sizes were small. Today, production is commercially economical. Diamonds can now be made in a relatively few minutes, and their performance in specific applications, discussed in the Natural Industrial Diamonds section, equals that of natural diamond.

Several types of manufactured diamond, both domestic and foreign, are now on the market, and each has distinct characteristics. Synthetic industrial diamonds are superior to natural diamonds because their properties can be tailored to specific applications and

they can be produced in large quantities. Metal coating of the diamond improves the adherence of the bond to the abrasive in resinoid bonded grinding wheels. Metal-coated (nickel, copper) diamond represents still another commercially available diamond type. Resin-bonded diamond grinding wheels are used in the production of cement carbide tools. Metal bond and electroplated diamond wheels are used in glass cutting and finishing. Polycrystalline diamonds (PCDs) are formed under high pressure and temperatures, resulting in thousands of microcrystallites bonded together. PCDs have self-sharpening properties: the polycrystalline structure allows new sharp edges to be available by releasing an outer layer of dull microcrystallites. Other properties of PCDs are high wear resistance, high shock resistance, good thermal stability, and a homogeneous structure. PCDs are used in drilling bits, wire-drawing dies, and reaming shells. A newly developed method from Apollo Diamond Inc. for growing gem-quality as well as industrial-grade diamonds is chemical vapor deposition (CVD). This technique transforms carbon into plasma that is then precipitated onto a substrate as diamond. This method has been used in the past to cover large surfaces with microscopic diamond crystals, but now Apollo has developed a method to create a single diamond crystal (Olson 2003b). Another advantage of CVD is finer control of impurities over the PCD method. The CVD diamonds can be used to fashion surgical blades that are resistant to dulling (Yarnell 2004).

The use of manufactured diamond has steadily increased. In 1969, domestic production of manufactured industrial diamonds amounted to approximately 13 million carats. By 1981, productivity had soared to approximately 57 million carats. In 2004, two U.S. producers of synthetic diamonds estimated an output of 250 million carats. More than 88% of the industrial diamond market now uses synthetic diamonds because of quality control and customization for specific requirements (Olson 2005b). Nine U.S. firms manufactured PCDs from synthetic diamond grit and powder (Olson 2005b). Recycling has become important as well; an estimated 4.4 million carats were recycled in 2004 from bort, grit, dust, and powder. Additionally, an estimated 275,000 carats of diamond stone were recycled. Lower prices for newly produced industrial diamonds reduced recycling operations from 4.9 million carats in 2003. The United States continues to be the world's leading market for industrial diamonds and remains a significant producer. The Congo (Kinshasa) and Australia, are major producers as well.

Boron Nitride

Boron nitride in cubic form is a manufactured abrasive discovered by General Electric Co. Laboratories in 1957 and trademarked as Borazon. Unlike manufactured diamond, it has no known counterpart in nature. It is made at temperatures and pressures comparable to those required for diamond manufacture. The thermal stability of cubic boron nitride exceeds that of diamond. It is stable at temperatures greater than 1,371°C, whereas diamond reverts to graphite at greater than 816°C. The Knoop hardness (K100) is 7800, well above ordinary abrasives but inferior to diamond.

Borazon is used in industrial applications to shape tools because it can withstand temperatures greater than 2,000°C. Cutting tools and abrasive components, particularly for use with low-carbon ferrous metals, have been developed using cubic boron nitride. In this application the tools behave in a similar manner to PCD tools but can be used on iron and low-carbon alloys without risk of reaction.

Metallic Abrasives

Metallic abrasives include crushed steel, steel shot, angular steel grit, steel wool, brass wool, and copper wool. The following

description of the first three of these products is by Johnson and Schauble (1939):

Crushed steel is made from high-carbon and crucible sheet steel specially treated to impart brittleness. It is then crushed to sizes ranging from 2- to 200-mesh. After screening, each batch is heat-treated and separated into 25 sizes ranging from 20- to 200-mesh. Sizes from 70-mesh upward are screened on silk bolting cloth, and the finer sizes in powder form are used in steel cement, various chemical compounds, and fireworks sparklers.

Steel shot is merely chilled cast iron. Only raw materials of the highest grade, including selected scrap and charcoal iron are used in its manufacture. These are melted in a cupola. During the casting period, the molten metal is separated into small spherical globules by directing high-pressure steam or heated compressed air against the stream of metal. The globules are blown into water and cooled. The shot, made brittle by the rapid cooling, is heat-treated to impart a temper of hardness and graded by mechanical means into 15 sizes that range from 4- to 90-mesh. Coarse material left on the 4-mesh screen is granulated by specially designed crushing equipment and in this form is known as angular steel grit. The crushed material is heat-treated to impart toughness and durability. It is then graded into 15 sizes ranging from 7- to 100-mesh. Steel shot and angular steel grit are used for many abrasive purposes.

Steel wool, made from both ordinary and stainless steel in various degrees of fineness, is used for finishing wood and soft metals such as aluminum, and for scouring and cleaning. It is made in several types of machines by shaving or scraping continuously moving wire with a fixed serrated cutting tool. Brass and copper wool are used chiefly for household cleaning.

Today, most metal abrasives (75%) are used as loose particles propelled at high velocities for blast cleaning or for improving the properties of metal surfaces. Industries using metallic abrasives include foundries, automotive and aircraft manufacturing, and metalworking and steel plants (Olson 2004).

Olson (2005a, 2003b) reported production, shipments, and annual capacities of metallic abrasives in the United States, by product, for 2002 through 2004. Table 6 shows total production of 194 kt valued at \$92 million are reported for 2004. Steel shot and grit accounted for 99% of the total metallic abrasives produced domestically. Seven companies reported production of cut wire shot in 2004, most cut from carbon-steel wire and stainless-steel wire. Other products include shot cut from aluminum, copper, and zinc wire (Olson 2004). The United States increased exports of metallic abrasives by 21% in 2004. More than 90% of these exports were to Canada and Mexico. The United States also imports metallic abrasives from 12 countries; 71% of imports are from Canada (Olson 2004).

Chemical Precipitates

Chemical precipitates, mainly oxides, all have a very fine grain size and are used as final polishing agents.

Iron Oxides. Rouge, a ferric oxide, has its largest use in polishing plate glass, but it is also widely used in powder, paste, coated cloth, and stick form for polishing precious metals, stone, and other materials to give a final high luster. Crocus is similar to rouge in composition, but purplish red in color. Crocus is used in finishing cutlery and some brass work.

Other Precipitates. Chromium oxide, or green rouge, is used chiefly for platinum and stainless steels. Tin oxide is used largely for polishing glass and precious stones. Putty powder is a mixture of tin oxide and oxalic acid used for polishing glass and precious stones. Cerium oxide is a polishing agent for glass and can be substituted for tin oxide in other applications. Magnesia in the soft precipitated form has been noted as a mild polishing powder. The hard-burned variety, artificial periclase, has also been used as an abrasive. Precipitated calcium carbonate is used as a mild abrasive in some dentifrices.

Calcium and Magnesium Oxides (Lime)

Lime (CaO), manufactured by calcination of limestone, and dolomitic lime (CaO•MgO), derived by calcination of dolomite, have important abrasive uses. This has been especially true of those marketed under the names of Vienna lime or Sheffield lime. The so-called Vienna lime (originally from Vienna, Austria), which is used on the American continent in a grease-brick buffing composition, is obtained from certain beds of dolomite at Francis Creek and Manitowoc, Wisconsin. Vienna lime is made by calcining the dolomite, then cleaning and grinding to a specific fineness. It is packed in carefully sealed containers. As soon as the lime becomes hydrated, it ceases to function and attacks the grease composition. This product is used for buffing brass, copper, bronze, steel, pearl, celluloid, and similar materials. Its principal use is for coloring nickel after plating. Vienna lime gives nickel a deep undersurface blue peculiar to the metal. Lime attacks aluminum and thus is not applied with this metal.

Miscellaneous Manufactured Abrasives

Porcelain. The use of porcelain blocks and pebbles for grinding mills has been noted. This porcelain may consist largely of zirconium oxides or silicate, or of mullite converted from andalusite, kyanite, or dumortierite.

Glass. Crushed and screened glass has been used for coated abrasives to make glass paper.

Lampblack. Lampblack, fine soot collected from incompletely burned carbonaceous materials, finds some use for polishing celluloid and bone.

Clay. Clay, burned to a very hard state and finely pulverized, is reported to have been used as an abrasive for polishing metal.

Government, Environment, and Health Considerations

One of the most important issues affecting the abrasives industry in recent years has been the potential effect of crystalline silica on human health. OSHA created a permissible exposure limit that stipulates the maximum amount of crystalline silica to which workers are exposed in an 8-hour work shift (29 C.F.R. 1926.55, 1910.100; U.S. Department of Labor 2002). This legislation has influenced the use of silica sand, diatomite, tripoli, and special silica stone as an abrasive.

Trends and Opportunities

Abrasives are used in almost every manufacturing and industrial sector of the economy and are greatly influenced by the economic and technological trends of these markets. Many natural abrasive materials have been replaced by synthetics, and that trend is likely to continue. Garnet is an exception, particularly in the water-jet cutting market, and abrasive blast cleaning has a bright future for market development. Garnet is replacing silica sand as a sandblasting agent because of the health risks.

With improved technology, surface quality requires less grinding and finishing, meaning less-coarse abrasives are required

(Harris 2000), creating a greater need for finer grades. Demand for industrial diamonds in the United States is likely to continue with growth in the construction sector, particularly with the rebuilding of the nation's highway system (Olson 2003b), where diamonds are used on the cutting edges of saws employed in highway construction and repair work. With the current housing construction boom in North America, the demand for manufactured abrasives used in cutting and finishing wallboard and timber will also continue (Olson 2004). Rising energy costs and falling prices influenced by a flood of imports from China have been, and will continue to be, a challenge to domestic production.

Construction Sand and Gravel

William Langer

INTRODUCTION

Sand and gravel are among the most familiar minerals in everyday life, and together comprise one of the two principal sources of aggregate. Crushed stone, the other source, is discussed in a separate chapter and is mentioned here only in a general manner, such as when both sand and gravel and crushed stone are being described as aggregate.

This chapter is intended to present a general perspective on the geology of sand and gravel deposits, and how they are explored, mined, and processed for aggregate to meet the needs of the construction industry. The transportation, marketing, specifications, and uses of sand and gravel are discussed only briefly in this chapter (for a more detailed discussion, see the Lightweight Aggregates chapter in this volume).

Most sand and gravel is used as construction aggregate. In many cases, it is preferred over crushed stone for use in portland cement concrete because its smooth, rounded shape allows for easy mixing without addition of excess water and cement. Gravel commonly must be crushed for use in asphaltic concrete where interlocking edges add strength. An average six-room house requires about 82 t of aggregate, and an average school building requires about 14,000 t of aggregate (Langer and Glanzman 1993). Sand and gravel also has numerous applications in an unbound state. The proportional share of aggregate consumed by each person in the United States is about 9 tpy, about 3.8 t of which is sand and gravel.

Definitions

Wide variations exist for the definition of sand and gravel; some terms have different meanings to different users. In addition, some terms have descriptive characteristics that are dependent on local conditions and, as such, serve an important function. The terms used in this chapter generally conform to geologic descriptions.

- Sand and gravel: a mixture of unconsolidated material resulting from the natural disintegration of bedrock and the subsequent transport, abrasion, and deposition of the particles by ice, water, wind, and gravity. Sand and gravel normally occur together and can contain particles ranging in size from clay to boulders.
- Sand: natural granular material resulting from rock disintegration, consisting primarily of particles having a diameter in the range of $1/16$ in. to 2 mm, according to the definition of Bates

and Jackson (1987). Manufactured sand resulting from the production of crushed stone is discussed in the Crushed Stone chapter in this volume.

- Gravel: unconsolidated, natural accumulation of rounded rock fragments resulting from erosion, consisting predominantly of particles larger than sand (diameter greater than 2 mm), such as boulders, cobbles, pebbles, and granules (Bates and Jackson 1987).

Production and Trade, Substitutes, and Resources and Reserves

Sand and gravel is the second largest nonfuel mineral commodity in the United States in both volume and value. About 1.13 billion t of sand and gravel, with a value of \$5.8 billion, was produced by an estimated 4,000 companies from 6,400 operations in 50 states (Bolen 2004). About 25% of the operations produce less than 25,000 tpy of sand and gravel. About 3% of the operations produce more than 1 Mtpy of aggregate and account for nearly 30% of the total sand and gravel production (Bolen 2002). About 10% of the operations account for more than half the annual production. About 53% of the 1.13 billion t of construction sand and gravel produced in 2003 was for unspecified uses. Of the remaining total, about 42% was used as concrete aggregates; 23% for road base and coverings and road stabilization; 15% as construction fill; 12% as asphaltic concrete aggregates and other bituminous mixtures; 3% for concrete products, such as blocks, bricks, and pipes; 1% for plaster and gunite sands; and the remaining 4% for snow and ice control, railroad ballast, roofing granules, filtration, and other miscellaneous uses (Bolen 2004).

Sand and gravel production, expressed as a percentage of total aggregate production, varies from state to state depending on a variety of reasons, including geology, availability, ease of obtaining permits, local or regional specifications, and operator preferences. Generally, in the United States, more crushed stone is produced than sand and gravel (Table 1). More sand and gravel than crushed stone is produced in 24 states.

The amount of foreign trade of construction sand and gravel is minor. During 2001, about 3.06 Mt were exported, and about 3.82 Mt were imported. Most trade is with Canada and Mexico.

Total world production of aggregate (including crushed stone as well as sand and gravel) is estimated at 15 billion tpy. Production in the European Union is about 3 billion tpy, representing about two

Table 1. Sand and gravel production, by state, for 2002

State	Sand and Gravel Value, \$1,000	Sand and Gravel Production, kt	Sand and Gravel as Percentage of Total Aggregate Production	State	Sand and Gravel Value, \$1,000	Sand and Gravel Production, kt	Sand and Gravel as Percentage of Total Aggregate Production

thirds of the European total (Regueiro et al. 2002). Aggregate production rates plummeted in Eastern Europe following the political reorganization of the early 1990s. More recently, production rates have stabilized, resulting in modest increases in demand in countries with emerging economies. Approximate production in other major aggregate-producing countries, in metric tons per year, follows: China, 4.5 billion; Japan, 550 million; Russia, 432 million; and Canada, 385 million (Regueiro et al. 2002).

Although aggregate resources, like all nonrenewable resources, are finite, the potential worldwide supply of aggregate resources is so large that "finite" loses its urgency in this context. But natural aggregate of suitable quality for an intended use can be in short or nonexistent supply on a regional or local scale because of unfavorable geology, encroachment by incompatible land uses, and the inability to obtain necessary permits.

A number of materials may be used as a substitute for sand and gravel. The most widely used one for gravel is crushed stone; for natural sand, it is manufactured sand. Other substitutes include recycled concrete or asphalt, slag, and shells.

GEOLOGIC ORIGIN AND MODES OF OCCURRENCE

The distribution and size of deposits of sand and gravel are primarily controlled by glacial, fluvial, and marine processes (Langer 1988). Wind is an inconsequential geologic agent when considering gravel. Consequently, sand and gravel is widely distributed and abundant near present and past rivers and streams, in alluvial basins, along marine or lake shorelines, and in previously glaciated

areas (Figures 1 and 2). The debris from in situ weathering of some bedrock can also be a source of sand and gravel.

Glacial Deposits

The most recent episodes of glaciation took place over the last 2.5 million years during which much of the world's temperate zones were alternately covered by glaciers and uncovered during the warmer interglacial periods. A number of ice sheets expanded from Canada into the northern tier of conterminous states and Alaska, at times covering all of New England; almost all of New York; all of Michigan; parts of Wisconsin and Iowa; almost all of Minnesota and North Dakota; and some of New Jersey, Pennsylvania, Ohio, Indiana, Illinois, Missouri, Nebraska, South Dakota, Montana, Idaho, Washington, and Alaska (Mickelson and Colgan 2004; Booth et al. 2004). These ice sheets persisted until about 11,000 years ago, and remnants occur in Alaska, Canada, and the higher portions of some Rocky Mountain states. Extensive ice fields and valley glaciers were found in the high ranges in all of the mountainous western states (Pierce 2004). These glaciated regions generally contain abundant deposits of sand and gravel, although glaciated areas exist where sand and gravel is absent or is covered with sufficient fine material to make discovery or exploitation uneconomical.

As glacial ice melts, rock particles that had been crushed, abraded, and carried by the ice are further transported, abraded, and rounded by meltwater. These deposits are potential sources of sand and gravel that are of great importance for use as aggregate. The particle size in the glacial meltwater deposits ranges from boulders

to sand, silt, and clay, and can change abruptly, both with depth and laterally, especially where the material was deposited under the ice (eskers, for example) or on or near the ice (moraines or kames, for example).

In some areas near the ice margins, large lakes were formed when meltwater was trapped between the ice and higher ground. For example, Lake Agassiz covered an area of about 365,000 sq mi (945,000 sq km) in Manitoba, Ontario, and Saskatchewan in Canada, and North Dakota and Minnesota in the United States; and the Great Lakes were once much larger than at present. Deltas formed where glacial meltwater streams emptied into these and numerous other smaller temporary lakes. These glacial lake deposits are important sources of high-quality aggregates.

Pluvial Lakes

In the Great Basin of the United States, a large number of closed basins exist. During the cooler weather that prevailed in that area during glacial times, precipitation was greater than it is today, and water did not evaporate as rapidly. Many closed basins contained large lakes, such as Lake Bonneville (of which Great Salt Lake in Utah is a remnant) and Lake Lahontan (of which Pyramid Lake and Walker Lake in Nevada are remnants). Fifty or more other lakes have since disappeared. Sand and gravel was deposited along the shorelines of some of these lakes. The old shorelines of former Lake Bonneville are a conspicuous landform at Salt Lake City. These types of beach deposits are a large potential supply of sand and gravel resources.

Marine Beaches and Terraces

During periods of glacial retreat, much of the glacial ice melted and the water returned to the oceans, causing the sea level to rise. Some inland areas of today were once coastal beaches or terraces, such as strandlines along the Atlantic and Gulf coasts. These are important sources of sand and gravel, although the gravel in some of the older deposits has deteriorated due to prolonged weathering.

Marine Offshore Deposits

In Europe, Japan, and elsewhere, marine (offshore) sand and gravel deposits are economically exploited for use as aggregate. Marine sand and gravel deposits are located on the continental shelf of North America along the Atlantic, Pacific, and Gulf coasts. Gravel is most common offshore from Canada, New England, New York, and New Jersey on the Atlantic Coast, and from Canada, Washington, and Oregon on the Pacific Coast. Gravel occurs infrequently in southern coastal areas of the United States.

Some sands obtained from U.S. federal waters have been used for beach renourishment, and sand and gravel has been recovered from dredging projects. Otherwise, marine deposits have generally not been commercially exploited in the United States.

Alluvial Deposits

In many states, alluvial (river) sand and gravel, either in the channels or floodplains of rivers and streams, or in terraces found alongside the rivers or streams, are the principal sources of sand and gravel. Alluvial sand and gravel deposits are products of bedrock erosion and the subsequent transport, abrasion, and deposition of the particles. The availability and quality of the gravel is strongly dependent on occurrence and properties of nearby bedrock sources.

If a river or stream changes gradient and downcuts its channel, the older channel and floodplain deposits may be preserved as river terraces. Repeated downcutting can result in a series of terraces or terrace remnants above the level of the modern stream base, which can be sources of sand and gravel. Older terraces may be exposed to

Figure 1. Generalized distribution of sand and gravel in the conterminous United States

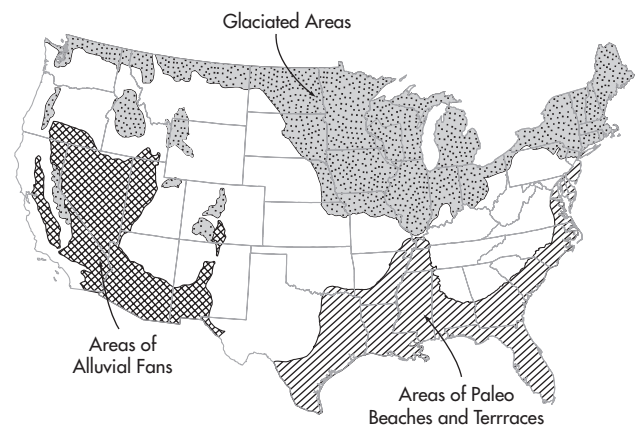

Figure 2. Generalized sand and gravel regions in the conterminous United States

prolonged weathering, thus weakening the material and reducing its suitability as aggregate.

Alluvial Fans

In mountainous arid and semiarid regions of the western United States, rock fragments are eroded and transported during storms down steep-gradient streams to the adjacent basins. Upon reaching the basins, the suddenly reduced sediment capacity of the water causes deposition, resulting in alluvial fans. These deposits commonly contain thick unconsolidated material ranging from large boulders to clay-size particles. Generally, the largest material is deposited adjacent to the mountains and becomes progressively finer toward the downstream edge of the deposits. Over time, fans from adjacent valleys can coalesce to form continuous, thick deposits. Sand and gravel in alluvial fans may be suitable for aggregate, but much of the material is poorly stratified and poorly sorted. In older fans the gravel may be highly weathered and not suitable for aggregate. In addition, fan gravels may be cemented with caliche, a calcium carbonate precipitate in the soil, making them difficult to extract and process.

In Situ Weathered Rock

In some areas physical or chemical weathering can disaggregate rock in place, resulting in a coarse lag material that sometimes is

used as sand and gravel. Rock types that are particularly susceptible to this type of weathering include conglomerate, sandstone, and coarse-grained granitic rocks. In some situations, the lag gravels may contain considerable fine material and require additional processing.

PROPERTIES

Some properties, such as mineralogy, density, and porosity, are inherent in sand and gravel particles. Other properties, such as size, shape, and sorting, are acquired as the result of processing the deposit. The properties discussed in this chapter are the inherent properties.

Sand and gravel is always of secondary origin and commonly reflects the petrology of the local rock types. An exception occurs in glaciated terrains where deposits can contain exotic rocks transported long distances by ice. Sand and gravel deposits may be composed of materials in which a single mineral dominates or may consist of a wide variety of rocks and minerals.

The properties of sand and gravel result from the petrology of the source rocks, the method of transport and deposition, and the subsequent weathering of the aggregate particles (Langer 2001b). Sand and gravel should be durable and strong, which means they should support the intended load and resist mechanical breakdown resulting from the action of mixers, mechanical equipment, and/or traffic. Particles should be sound, which means they should be able to resist weathering, such as repeated freezing and thawing or wetting and drying. Sand and gravel should be composed of clean, uncoated particles of proper size and shape for the intended use. Sand and gravel commonly meets these requirements, because the natural abrasion processes associated with the formation of most sand and gravel deposits tends to eliminate weaker particles.

The quality of the aggregate is defined most often by its conformance to specifications set by the user. Because aggregate commonly is used in highway construction, those specifications are usually set by state departments of transportation. Most states conform to the grading and testing standards of the American Association of State Highway and Transportation Officials (AASHTO) or the American Society for Testing and Materials (ASTM).

Physical Properties

The producer has little control over certain properties of individual particles in a deposit. These are particle size, shape, strength, specific gravity, porosity, and petrology. Size and shape can be modified if the gravel clasts are sufficiently large and can be processed by crushing and screening. If the properties do not meet local specifications, the deposit probably is not economically exploitable.

Particle Size and Size Distribution

Aggregate for most construction applications can be prepared from sand and gravel deposits containing a wide range of particle sizes. Particle-size distribution of sand and gravel deposits can be quite variable, both laterally and vertically. The larger the gravel-to-sand ratio, the better the deposit (Langer and Knepper 1998), except in areas where crushed stone is abundant and natural sand is lacking. Silt and clay occurring either as layers, interstitial material, or as coatings on larger clasts are undesirable. Silt-sized or smaller fine particles generated from crushing gravel are also undesirable.

Particle Shape

Three techniques are commonly used to describe particle shapes of naturally occurring gravel. One technique, commonly used by geologists, compares the lengths of three diameters of the particle and describes them as equidimensional, disk, blade, or rod shaped (Langer and Knepper 1998). Another technique, commonly used by

engineers, utilizes a proportional caliper to determine the ratio of the maximum-to-minimum dimensions. A third technique visually estimates shapes and describes them using terms such as rounded, flaky, and elongate (Marek 1991). Particle shapes tend to be beneficial when the predominant shape is equidimensional and detrimental when the predominant shape is disk, blade, or rod shaped (Langer and Knepper 1998). Particles can also be described based on the angularity of their edges and can be divided into a number of classes from round to angular. The desired roundness or angularity depends on use.

Specific Gravity

Specific gravity is the ratio of the mass of a given volume of aggregate to the mass of an equal volume of water. Very low specific gravity frequently indicates aggregate that is porous, weak, or absorptive; high specific gravity generally indicates high-quality aggregate. Bulk specific gravity is the ratio of the weight of a given volume of material, including all voids, to the weight of an equal volume of water. Apparent specific gravity is the ratio of the weight of a given volume of material, including all impermeable voids, to the weight of an equal volume of water.

Porosity and Pore Structure

Porosity is the percentage of the total volume of a gravel particle occupied by pore spaces. Pore structure is the size, shape, volume, and interconnectedness of the spaces within an aggregate particle. Pores can be impermeable (isolated, enclosed cavities) or permeable (interconnected and connecting to the surface of the particle). Gravel particles with high permeability are not desirable for most applications because they absorb large volumes of water or salt solutions, thus reducing soundness. For bituminous mixtures, high permeability also increases the absorption of binder, thus increasing the cost of the paving mixture (Barksdale 1991).

An approximate inverse correlation exists between aggregate quality and rock porosity. Porosity affects the strength and elastic characteristics of an aggregate, and may influence permeability, absorption, and durability. Rock with water absorption of 2% or less will usually produce good aggregate, whereas otherwise suitable rocks with a water absorption that exceeds 4% may not (Smith and Collis 2001).

Chemical Properties

The chemical properties of sand and gravel vary from deposit to deposit and within clasts, and commonly are identified through petrographic analysis. They are primarily controlled by the mineralogy of the individual particles. Most sand and gravel is considered to be inert, but it may contain minerals that adversely react with portland cement or bitumen and affect the product life.

Weathering and Impurities

Sand and gravel should not be excessively weathered. Weathering of gravel clasts lessens the strength of aggregate and increases the overall cost of mining and processing. Once sand and gravel has been deposited, it is subjected to natural weathering processes. The rate and type of weathering depends on the local climatic conditions, the geometry of the deposit, the relationship to the water table, and the properties of the sand and gravel clasts. Weathering can range from slight discoloration of the clasts, through the introduction of fractures and alteration of minerals, to complete decomposition and disintegration of the clasts. In arid and semi arid climates, sand and gravel may be cemented with caliche, a calcium carbonate, and may be difficult to extract and process. In humid regions, sand and gravel may be cemented or stained with iron or manganese dioxide. Sand and gravel must be free of objectionable

rocks, such as shale, mica schist, coal, and gypsum, and of roots and other organic material.

PROSPECTING, MINING, AND PROCESSING

Sand and gravel must physically be able to be mined and be accessible to transportation systems and to markets. The site must qualify for all necessary land use and environmental permits. The operation must be profitable considering all costs, including acquisition, operation, compliance with regulations, and reclamation (Dryer 1976; Banino 1994). These requirements usually make opening a new operation a complicated process that involves substantial cost and can take many years.

Prospecting Techniques

The U.S. Bureau of Mines Information Circular 6668 (Thoenen 1932) was one of the first comprehensive publications to describe sand and gravel prospecting techniques. The 3rd edition of *Industrial Minerals and Rocks* (Lenhart 1960) and all subsequent editions contain discussions on prospecting for sand and gravel. Dunn and Cutcliffe (1971) include socioeconomic factors as part of the exploration process. A chapter in *The Aggregate Handbook* (Dunn 1991) and a four-part series of articles in *Rock Products* (Timmons 1994, 1995) describe many aspects of both exploration and characterization of aggregate resources.

Exploration for sand and gravel has become more than simply locating a source of suitable material and commonly is based on the principle of the weakest point (Dunn 1991). During exploration, a weakest point exists that should be analyzed before proceeding to other elements of exploration. For example, it may be unwise to intensely study sand and gravel deposits in an area where fragmented land ownership makes acquisition difficult. It would also be unwise to thoroughly address all permitting requirements before determining some estimate of the quality of a deposit. Thus, exploration requires judgment and experience in order to proceed in a logical sequence. Each weak point should be resolved to an acceptable level of risk before proceeding to the next weakest point (Dunn 1991).

When assessing preliminary target areas for sand and gravel exploration, economic and social factors such as markets, transportation options, current land use, zoning regulations, and property ownership should be considered. Public hearings commonly are held before governmental bodies such as county or town boards, and the public and governmental views toward aggregate production must be carefully analyzed (Dunn 1991).

Exploration for sand and gravel deposits within target areas commonly begins with desktop studies utilizing existing data. Detailed geologic maps and cross-sections for large parts of the United States and elsewhere can be used to help locate sand and gravel deposits. Hydrologic reports of alluvial areas frequently contain logs of wells and test holes. In glaciated terrain, geologists commonly can readily identify typical glacial features that are likely to contain sand and gravel by using topographic maps with a contour interval of about 5 m or less, and large scale (about 1:50,000 or larger) aerial photographs. Geologists can also identify stream terraces, floodplains, alluvial fans, and beach deposits in many nonglaciated terrains using the same type of maps or photographs.

In developing areas or other locations where existing large-scale geologic information and other map data are inadequate, remote sensing data (satellite or airborne spectral imagery) and airborne geophysical surveys may be useful for detecting sand and gravel resources. Knepper, Langer, and Miller (1995) reviewed a number of techniques that have been successfully applied in locating

sand and gravel. These include the use of satellite data, in some instances in conjunction with aerial photographs, to delineate gravel-filled paleochannels (USGS 1981), buried gravel deposits (Peterson, Goodrick, and Melhorn 1975), and calcrete for use as roadstone (Henry 1989). Sand and gravel has been identified using satellite or airborne thermal infrared data to detect differences in diurnal (Carr and Webb 1967) and soil-moisture temperatures (Jackson et al. 1978; Schmugge, Jackson, and McKim 1980; Sabins 1984). Knepper, Langer, and Miller (1995) also describe the application of airborne very low frequency (VLF) resistivity surveys to locate exposed gravel deposits (Middleton 1977) and buried gravel deposits (Culley 1973).

Field studies commonly are conducted to check the veracity of desktop analyses and collect new data. These activities may include a comparison of the geomorphology, as observed in the field, with the desktop interpretations of the topographic and aerial photographic analyses. Natural and synthetic exposures are investigated and sampled to determine the extent of the deposit, sand and gravel properties, and subsurface conditions. A geologist may also evaluate the site to identify potential environmental factors and to prepare plans for more detailed site evaluation.

Detailed Evaluation of Deposits

If reconnaissance studies indicate a target area worthy of further investigation, the next step is more detailed field studies. Acquisition of more detailed information increases costs, and it is appropriate to assess the weakest point at this stage of exploration. Economic and social factors, such as current land use, zoning regulations, and property ownership, might be investigated in more detail, particularly because it will be necessary to obtain permission from landowners to access sites for further studies.

Systematic sampling should be conducted to determine the areal extent, thickness, stratigraphic variation, and physical properties of deposits. Test pits, truck-mounted augers, and other truck-mounted drills commonly are used to determine the factors as well as to obtain samples to find out the properties of the sand and gravel. A power hoe can dig test pits or trenches about 4 or 5 m deep. Truck-mounted augers have a capacity to drill to depths of about 60 m. Auger sizes range from about 6 to 60 cm, with the most common sizes between 10 and 15 cm. Deposits of cobble and boulder gravel are difficult for augers to penetrate and may require the use of other drilling equipment.

The spacing of drill holes, test pits, and trenches, and remote sensing patterns are site specific and should be based on the predictability and geologic continuity of the deposit's critical characteristics as determined by qualified personnel experienced in such procedures (Dunn 1991; Timmons 1994). Sample spacing depends on the desired level of detail and needed confidence, and typically ranges from 30 m in highly complex areas to as much as 500 m in large areas of very simple geology. Sampling plans may be modified based on updated knowledge gained during ongoing site characterization.

Electrical resistivity techniques were used to explore for sand and gravel prior to the late 1930s (Patterson 1937). Techniques used today include direct current resistivity (DCR) soundings, time domain electromagnetic (TEM) soundings, ground-penetrating radar (GPR), and seismic refraction.

Properly conducted surface geophysical surveys can provide information on the areal extent and thickness of the deposit, thickness of overburden, stripping ratios, depth to the water table, and critical geologic contacts. They are appropriate for a quick location and correlation of geologic features such as silt and clay lenses. Surveys can be run where closely spaced geological changes might

be undetected by drilling, such as areas of suspected buried channels, and where other elusive, but important, geologic conditions may exist.

Geophysical surveys can be conducted to provide subsurface detail in areas where digging test pits, augering, or drilling are encumbered because of limited access. Landowners may prohibit invasive exploration activities, such as drilling or digging test pits, or restrict vehicular access to existing roads. Augering, drilling, or digging test pits might be unacceptable in some areas such as active cropland or forested land. Auger trucks or drill rigs may be unable to reach sample areas if the ground surface is soft, muddy, or covered with water. The geologic properties of the target deposit may confound augering—for example, where deposits contain cobble-sized or larger clasts. Additional problems related to drilling are described by Timmons (1995).

Geophysical surveys can be of value when performed early in the field exploration program in combination with limited subsurface investigations. Such surveys, when conducted prior to intensive drilling, can be used to help locate auger or drill holes and can reduce the number of test drilling sites. Geophysical surveys can provide continuity between sampling sites in order to upgrade the confidence of reserve calculations from probable reserves to proved reserves.

An experienced field geologist can determine whether or not a geophysical survey is warranted and which methods should be used. The spacing of geophysical survey patterns is site specific and should be based on geologic characteristics of the site and the predictability of continuity of the deposit's critical characteristics as determined by personnel specially trained in such procedures (Dunn 1991; Timmons 1994). Survey plans commonly are modified during site characterization based on knowledge gained during the sampling process.

Ellefson, Lucius, and Fitterman (1998) tested the effectiveness of DCR, TEM, GPR, and seismic refraction using S-waves to characterize sand and gravel. Haeni (1995) similarly tested DCR and seismic refraction using P-waves. In most cases, useful geologic information, such as sediment thickness, was obtained with all methods. Shortcomings include the presence of clay-rich soil limiting the effectiveness of GPR and the difficulties of P-wave seismic studies used below the water table.

The results of geophysical surveys are limited because it is not possible to translate geophysical data without correlative evidence normally provided by borings. In addition, geophysical surveys generally provide a very broad guide to the characteristics of a sand and gravel deposit that must be refined by other means. Actual subsurface information is desirable so that geophysicists have an idea of what to expect when measuring resistivities. The presence of conductive fluids in pores and of synthetic conductors such as fence posts and pipes can create erroneous results.

All critical variations in the geologic characteristics of a sand and gravel deposit should be recorded. Geologic mapping systematically documents field observations and is a valuable tool for planning drilling and sampling locations (Dunn 1991), assessing geophysical needs, establishing background data, and identifying potential environmental impacts associated with aggregate development. Geologic maps, cross-sections, and accompanying reports of potential sand and gravel operation sites commonly show the location and outline of the deposit, location of sampling sites and geophysical surveys, thickness of the deposit, and descriptions of materials throughout the deposit. Supplemental maps and reports can also describe related issues such as the thickness of overburden, depth to ground water, and geologic hazards. In many states, such reports must be prepared by a licensed professional geologist.

The difficulty of calculating volumes of deposits has been greatly simplified with the use of specialized mining and quarrying software, the geographic information system (GIS), and computer-aided design (CAD) software. Usable volumes exclude areas of setbacks, access roads and other infrastructure, maintenance facilities, and so forth. Information obtained during geologic mapping and sampling can be entered directly into these programs, and resource volumes can be calculated using various algorithms. For people who choose not to use computers, other methods exist to calculate volumes of deposits (Peters 1987).

Gross reserve tonnage is calculated by multiplying the unit weight of sand and gravel by the estimated usable volume. The unit weights of sand and gravel varies widely from deposit to deposit and is sometimes arbitrarily considered to be 1.78 t/m³. The in-place density of deposits can be determined more accurately by weighing the contents of an excavated known volume.

Net reserve tonnage is the percentage of the gross reserve that can be made into usable products. Excluded are overburden, fines and other waste, and uncrushable oversized boulders.

There are numerous methods for appraising sand and gravel pits depending on the purpose of the appraisal and the status of the pit (Paschall 1998; Evans 1995), but for industrial minerals such as sand and gravel, economic and legal issues usually are far more important than the geologic aspects of a deposit. Companies perform detailed reserve estimates and appraisals for a variety of reasons, including sale or purchase of undeveloped resources or reserves, acquisitions and mergers, valuation of a mining property, accounting, financing, taxation, condemnation, mineral conservation, and for internal planning. Customers or investors can precipitate an analysis of reserves by demanding proof of the existence and quality of reserves before committing to long-term purchase agreements.

Mining

Site preparation starts with grubbing and stripping sufficient overburden to access the resource. Often required by regulation, topsoil commonly is separated from the overburden and stockpiled for reclamation activities. Overburden may be used to construct berms, be stockpiled, or sold. Soil or overburden should not be stockpiled over parts of the deposit where future extraction is expected, and final need for reclamation should be considered. Site preparation also includes construction of access roads, fences, berms, haul roads, drainage ditches, culverts, settlement ponds, processing and maintenance facilities, and other plant infrastructure.

Sand and gravel is mined from open pits and dredged from underwater bodies. In upland areas, such as high terraces and some glaciofluvial deposits, sand and gravel may occur as unsaturated deposits. Where sand and gravel mining does not penetrate the water table, the aggregate can be extracted by using conventional earth-moving equipment.

In some areas, such as low terraces and glaciofluvial deposits, the pit may extend into the water table. In some geologic settings, wet pits can be dewatered by collecting the groundwater in drains on the pit floor and pumping the water out of the pit, or by isolating the pit from the groundwater through the use of slurry walls. In some situations where the sand and gravel pits penetrate the water table, such as floodplains or low terraces, the pit may be allowed to fill with water, and the operator may extract the material by using wet mining techniques such as draglines, clamshells, bucket and ladder, or hydraulic dredges.

Sand and gravel can be excavated directly from stream channels or from the edge of stream channels. During times other than flooding, aggregate can be skimmed from bars in channels or from

active floodplains. Stream channels may be temporarily or permanently diverted to allow for aggregate extraction using conventional earth-moving equipment in the natural streambed. A variety of methods can be used to divert the channel, including the construction of a new diversion channel, split-channel mining, and the construction of harvest pits (Colorado Division of Minerals and Geology 1998). In arid areas, some stream channels or washes only occasionally have stream flow, and sand and gravel can be mined from the channels using conventional excavation equipment.

Processing

After extraction, sand and gravel occasionally is used as-is, which is called bank-run or pit-run gravel; most frequently, it is processed before use. Processing may be as simple as a portable crusher and screens or can be a highly automated, sophisticated procedure. There are numerous ways to configure equipment depending on the characteristics of the sand and gravel deposit and its final use. Figure 3 is a flow diagram showing the generalized processing steps.

Material to be processed commonly is transported from the pit face to the processing plant by conveyor or haul truck. The material may be processed to remove lumps of clay, which can plug processing equipment and contaminate the final product. Deposits containing boulders may be fed through a “grizzly” screen to remove boulders too large to go through the crusher. The material is stored in a surge pile. A gate at the bottom of the surge pile releases a controlled amount of sand and gravel to a screen where the sand is separated from the gravel.

Gravel follows one path through the process; sand follows another. If the gravel is larger than about 1 to 1.5 in. (2.5 to 3.81 cm), it is crushed and screened to separate properly crushed particles that go through the screen (“throughs”) from those that go over the screen and back into the crusher (“oversized”). Throughs pass over a series of screens to divide the gravel into specific particle sizes. Gravel may be washed to remove fine particles. Conveyors move the sized gravel to separate stockpiles awaiting sale. Sand is sent to a classifier where it is tailored for its final use (such as asphalt, portland cement concrete, or masonry sand). Waste fines are sent to a settling pond.

Procedures must be followed carefully when stockpiling and handling the final product. The processing of aggregate requires significant effort and cost to prepare a product that meets exacting specifications for grading, freedom from contaminants, and other requirements. Mishandling of aggregate can result in significant degradation of the product (Rollings and Rollings 1996). When aggregate falls too far from conveyors onto coned stockpiles, when it is dumped from trucks down a slope, or when equipment pushes it over long distances, the material can separate from a well-blended product into individual size fractions. Improper handling can also result in contamination of the aggregate with foreign material from underneath the stockpile.

Upon sale, the stockpiled material may be sold as a single-size product, or two or more materials may be blended to make a new, graded product. For example, sand and properly sized gravel may be mixed in specific proportions to be used with cement to make concrete.

REGULATORY AND ENVIRONMENTAL CONSIDERATIONS

Regulations

Sand and gravel mining is permitted or controlled at the federal, state, and local levels of government by numerous governmental agencies (Arbogast 2002). All states are subject to federal law, whether land within state boundaries is federal, state, or privately

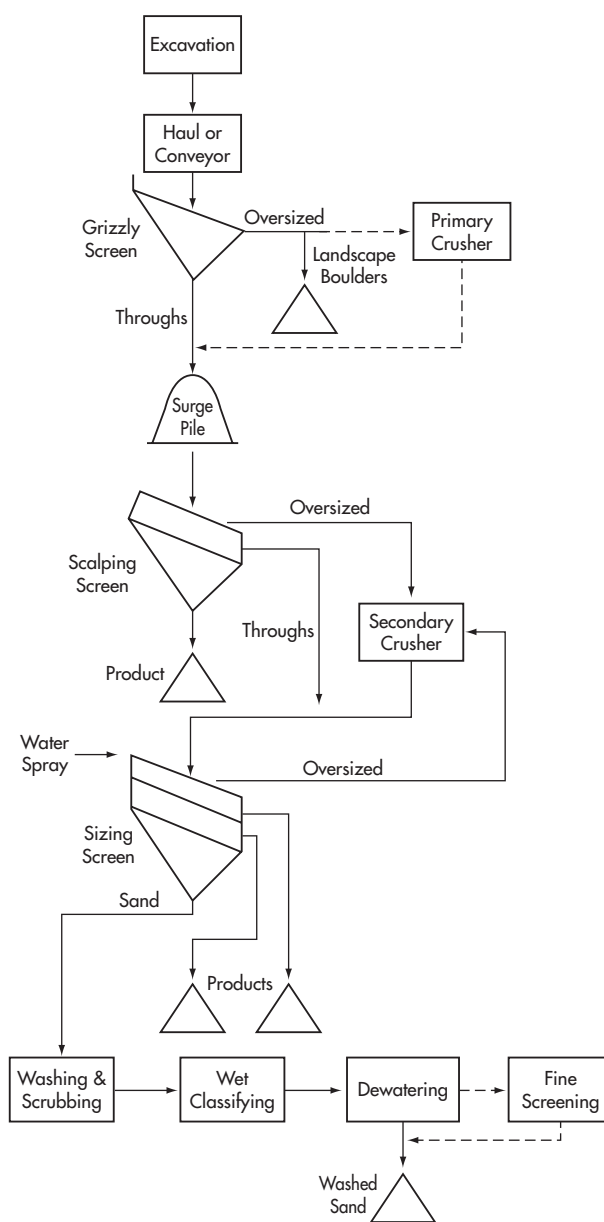

Figure 3. Diagram showing typical sand and gravel processing

owned. Indian tribal lands are considered sovereign and are subject to federal law, but without state jurisdiction or taxation.

Approximately one third of all land in the United States, most of it in the westernmost conterminous states and Alaska, is owned by the federal government. The agencies managing most of those lands are

- Bureau of Indian Affairs
- Bureau of Land Management
- Bureau of Reclamation
- National Park Service
- U.S. Army Corps of Engineers
- U.S. Fish and Wildlife Service
- U.S. Forest Service

The General Mining Act of 1872 encouraged exploration of federal lands for mineral resources, including common minerals. In 1955 Congress removed common construction materials (termed “salable minerals,” including sand and gravel) from the mining law and made them available through a contract or bidding process at the discretion of the land management agency (Arbogast 2002).

The Water Quality Act of 1965 and the Federal Water Pollution Control Act Amendments of 1972 (retitled the federal Clean Water Act) were enacted to provide efficient programs of water pollution control. Every major point source (a confined conveyance such as a pipe, drain, or ditch) from which pollution is discharged into U.S. waters requires a joint federal–state permit (Arbogast 2002).

The Air Quality Act of 1967 (amended by the Clean Air Amendments of 1970) gives states and local governments the responsibility to develop and implement plans to address airborne pollution at its source. Sand and gravel mining activities that are covered include dust and exhaust emissions (Arbogast 2002).

Other federal regulations indirectly control the production of aggregate resources through numerous acts, including the Fish and Wildlife Resource Management Act, the Fish and Wildlife Coordination Act, the Migratory Bird Treaty Act, the Endangered Species Act, including the Rivers and Harbors Act, the Coastal Zone Management Act, and the National Environmental Policy Act. The operation of sand and gravel mining is controlled at the federal level by the Mine Safety and Health Administration (MSHA).

Each of the 50 states has a different process to obtain permission to extract minerals. Some states issue permits for aggregate mining; others leave that authority with local agencies. The result is inconsistent policies among states and between the states and the federal agencies. Commonly, state agencies enforce federal regulations such as air quality, water quality, diversion or impoundment of surface water, and withdrawal of groundwater.

In a review of various state mining laws, Arbogast (2002) found that state laws related to mining vary greatly. At least 37 states regulate non-coal surface mining on a statewide basis. Thirty-five states require some sort of bond or security from the operator. At least 26 states provide for public comment at permit review. Some states have no legislation to regulate sand and gravel mining. In other states, sand and gravel mining is regulated at the local level.

The federal government encouraged state and local governments to create zoning codes through the Standard State Zoning Enabling Act of 1922. The authority of governments to enforce zoning regulations was upheld by the Supreme Court in 1926 in the landmark case of *Village of Euclid, Ohio v. Ambler Realty*. Since then, every state has enacted zoning legislation. Many, but not all, states transfer zoning authority to county or municipal authorities. Some rural areas in the United States, however, remain unzoned.

The United States is made up of more than 3,000 counties and many more local governmental authorities. Counties and other local governments may or may not have final permitting authority for sand and gravel mining. Even where local governments do not have this authority, they commonly influence the final land-use decision by controlling land-use activities such as ground disturbance, grading, noise, traffic, aesthetics, storm water, erosion and sedimentation, land use, building codes, hours of operation, and regulation of utilities. Approval of sand and gravel mining is frequently contingent on these issues (Arbogast 2002).

Environmental Considerations

Two reference documents dedicated to the aggregate industry that address environmental impacts from aggregate mining are by Barksdale (1991) and Smith and Collis (2001). Five comprehensive

collections of individual papers that describe many issues related to aggregate development are the International Association of Engineering Geology (1984), Kelk (1992), Lüttig (1994), Bobrowsky (1998), and Kuula-Väisänen and Uusinoka (2001). These papers, as well as information from other journals, are summarized by Langer (2001a). Langer, Drew, and Sachs (2004) describe potential environmental impacts from aggregate extraction and methods to control those impacts. A study of these reports provides an understanding of the many different environmental impacts related to aggregate mining and also gives a historical perspective of the issues.

Sand and gravel deposits commonly occur in areas that are also favorable for other land uses. Frequently, urban growth occurs without any consideration of the resource below or any analysis of the impact of its loss. Prime aggregate resources are precluded from development if permanent structures such as roads, parking lots, houses, or other buildings are built over them. The value of the improvements probably will permanently prevent any further development of aggregate at those locations. Such a situation is referred to as “sterilization” of the resource. New aggregate operations may have to be located long distances from the markets, and the additional expense of the longer transport of resources must be passed on to consumers. Also, the new deposit may be of inferior quality compared with the original source, yet it may be used to avoid the expense of importing high-quality material from a more distant source. Any savings for aggregate may be offset by increased processing costs or decreased durability of the final product.

In addition to encroaching on aggregate resources, urban growth often threatens established aggregate operations. Some residents in the vicinity of pits and quarries object to the noise, dust, and truck traffic associated with the aggregate operation. Many citizens do not support mining, in part because they do not recognize the dependence of society on aggregate. Personal use of aggregate is very little, if any, and individuals may not recognize aggregate mining as a necessary land use, even though the need for the commodity is constant. For these and other reasons, citizens commonly prefer that stone and sand and gravel not be mined nearby (Langer and Glanzman 1993). This “not in my backyard” syndrome may restrict aggregate development. Furthermore, governments require permits, impose regulations, or establish land-use zones, some of which may preclude mining.

Poulin, Pakalnis, and Sinding (1994) concluded that sterilization, permits, and regulations restrict development or expansion of aggregate production in established areas more than any actual limitations of suitable resource availability. The failure to plan for the protection and extraction of aggregate resources often results in increased consumer cost, environmental damage, and an adversarial relation between the aggregate industry and the community.

Because sand and gravel mining is an extractive industry, it cannot be obtained from the landscape without causing environmental impacts, which are commonly engineering related. These impacts, which include conversion of land use, changes to the visual scene, loss of habitat, erosion, sedimentation, noise, and dust, generally receive the greatest public attention. Many of these impacts, however, are restricted to the mining site, start when extraction begins, occur only as long as extraction and processing take place, and are easy to predict and control using standard engineering techniques.

The extraction of sand and gravel from river and stream terraces, floodplains, and channels commonly attracts additional attention because it may conflict with other resources such as fisheries, aesthetic and recreational functions, or with the need for stable river channels. The floodplains and channels of many rivers and

streams can accommodate the removal of some portion of sand and gravel without creating adverse environmental impacts, provided that the mining activities are kept within the limits set by the natural system. The principal cause of impacts from in-stream and near-stream mining is the modification of natural characteristics beyond what the system can tolerate.

Reclamation

Mining sand and gravel resources creates economic wealth, and the facilities made from aggregate improve the quality of human life. Reclaiming the mine site and associated areas may also create additional wealth and improve the quality of life. Reclamation is a major step in environmental stewardship.

Arbogast, Knepper, and Langer (2000) provide a review of the literature for actual and proposed reclamation sites. In the expanding suburban areas of today, mined-out aggregate pits and quarries are converted into second uses, such as wildlife habitat, recreational areas, agricultural areas, parks, school grounds, high-quality lake-front housing sites, and a myriad of other land uses. A plan for reclaiming the disturbed land and its ecosystem should be a part of every plan to mine natural aggregate.

There is a growing appreciation for the reversionary value of sand and gravel operations. Reclamation is becoming a major factor in sustaining the environment and in creating habitat biodiversity. And the need for specific postmining land uses such as water storage is becoming an important consideration in mining. For example, local municipalities have condemned alluvial land and leased the land to aggregate operations for gravel extraction, with the end goal of creating water storage reservoirs. The postmining land uses are being offered as justification for gravel extraction permits.

OUTLOOK AND FUTURE TRENDS

The U.S. Geological Survey (USGS) calculates future sand and gravel production using a conservative value of 0.5% increase per year. At this rate, sand and gravel production would exceed 1.25 billion tpy by 2025. Even with an increasing market, the USGS anticipates an increasing gap between crushed stone and sand and gravel production with a move toward crushed stone (Tepordei 1997).

In the last few decades, the process to permit new sand and gravel reserves has become increasingly difficult, lengthy, and expensive. Regulations, more than actual resource availability, restrict development or expansion of aggregate in established areas (Poulin, Palkanis, and Sindig 1994). This trend, fueled by increased citizen opposition to disruptive land-use practices, is likely to continue. One area of particular concern is the in-stream mining of sand and gravel because of its potential for widespread environmental impacts; opinions differ on which impacts are the result of mining or other land uses.

The industry trend is toward large businesses with large operations and large output. Acquisitions of such companies are expected to continue, especially as a means to obtain their permitted reserves. Increased costs, combined with local opposition to aggregate operations in populated areas, will likely force the location of new operations into more remote localities. These large centralized plants will utilize rail, barge, or ship transport and will service one or more urban distribution centers. The automation of processing plants and bulk material handling systems will allow for larger production rates at reduced costs.

Imports from Canada and Mexico are likely to increase, but with strong environmental controls to offset the concern of exporting environmental problems from the United States to Canada and Mexico.

Integrated software for permitting, reserve calculations, mine design, mine operation, stockpile management, scalehouse operations, and reclamation have become available at reasonable costs. Machine guidance systems are available that use global positioning satellites to determine the position of excavating equipment with centimeter-level accuracy.

Silicosis is a potential environmental health issue that faces the sand and gravel industry. This disabling, sometimes fatal lung disease afflicts workers that are overexposed to respirable crystalline silica. Silicosis is an occupational disease that is not known to affect the general population. Possible measures to address the issue, in addition to dust control, include employee training on silica hazards, periodic medical exams of potentially silica-exposed workers, and exposure monitoring (Bailey and Sharpe 2003).

There is a slow but inexorable move toward implementation of sustainable resource management principles and best management practices by sand and gravel producers, particularly large U.S. and multinational companies. Sustainable aggregate resource management can be achieved in a practical sense by adopting the following simple principles (after Plant and Haslam 1999).

Planning, project design, approvals assessment, and site conditions should

- Maximize the economic value of the resource, by extracting as much material as possible from the disturbed area and for the most economically valuable use it can accommodate
- Minimize waste of the resource, by a voiding high grading (picking the best parts of the resource and spoiling the ability to extract the remainder) and by finding uses and markets for all of the disturbed material (e.g., turning crusher fines into "manufactured sand," thus reducing the need for natural sand sources in more environmentally sensitive areas; and blending of lower-quality with higher-quality material as long as product specifications can be met)
- Minimize social and environmental impacts, by planning that protects important resources from urban encroachment and protects growing communities from the nuisance impacts of poorly designed, poorly located, and poorly managed aggregate operations; by using best-practice designs and operations to control the effects of blasting, noise, dust, sediment erosion, and visual scarring in extractive and transport operations; and by providing for conservation of natural areas by management of buffer areas that maintain or enhance vegetation, wildlife habitats, and corridors
- Maximize rehabilitation of disturbed areas, by allowing for reclamation as part of the quarry/pit design process before extraction begins; by starting rehabilitation from day one; and by being flexible enough to allow advances in technology and for changing local needs
- Maximize community engagement, by involving the local community in planning activities through open visit days and community awareness and educational activities. (This may lead to a measure of community acceptance and a "social license to operate," which can be just as important as the official legal permits.)

Crushed Stone

William Langer

INTRODUCTION

Crushed stone is one of the most familiar natural resources used in everyday life and is one of the two principal sources of aggregate. Sand and gravel, the other aggregate source, is discussed in a separate chapter and is only mentioned here when describing both crushed stone and sand and gravel as aggregate.

The purpose of this chapter is to provide a general perspective on the geology of potential sources of crushed stone and on how that material is mined and processed to meet the needs of the construction industry. The transportation, marketing, specifications, and uses of crushed stone are discussed in the Aggregates chapter in this volume.

Most crushed stone is used as construction aggregate, commonly in the form of asphalt or concrete. In many cases it is required for use in asphaltic concrete, because the angular surfaces provide the needed intergranular strength. One km of a four-lane interstate highway requires nearly 50,000 t of aggregate (Langer and Glanzman 1993). The proportional share of aggregate consumed by each person in the United States is about 9 tpy, about 5.2 t of which is crushed stone.

Definition

Crushed stone commonly is produced by drilling, blasting, excavating, and crushing bedrock, although it may involve crushing large boulders or cobblestones. Crushed stone tends to have angular edges, and substantially all of its surfaces have resulted from the crushing operation. It differs from sand and gravel, which tends to be rounded and is naturally occurring.

Unusual Considerations Specific to Crushed Stone

Over six times more aggregate operations exist in the United States than all other types of mines combined (excluding coal). Consequently, crushed stone and sand and gravel operations are a much more common component of the landscape than other mining operations.

The value of most metallic minerals and high-value industrial minerals rests on their properties or combinations of properties, such as hardness, strength, flexibility, electrical properties, and resistance to acids. These minerals have a high "unit value" and commonly can be economically transported significant distances to their market areas. In contrast, aggregate has a high "place value" because it is a high-bulk, low unit value commodity that is expensive to transport

to the market (Bates 1969), so its location (place) is preeminent. Aggregate operations frequently are located near population centers.

Potential sources of crushed stone are undeveloped areas of near-surface bedrock, which often are elevated above surrounding areas and highly visible. These unspoiled bedrock areas frequently are cherished as public "open space," even though the land may be privately owned.

The prevalence of aggregate operations, their proximity to population centers, their visibility, and their inherent disruptive appearance make proposed crushed stone operations ready candidates for citizen opposition. Quarries commonly have a life span greater than 40 years, thus adding to the concerns of nearby residents.

PRODUCTION AND TRADE, SUBSTITUTES, RESOURCES, AND RESERVES

Crushed stone is the largest nonfuel mineral commodity in the United States in terms of volume and value. During 2004, about 1.6 billion t of crushed stone, with a value of nearly \$9.7 billion was produced by an estimated 1,200 companies from about 3,200 surface and underground quarries (Tepordei 2005). Surface quarries are spread out over 47 states, whereas most underground quarries are in the central United States (Tepordei 2002). About 12% of the crushed stone operations produce less than 25,000 tpy of crushed stone. About 14% of the operations produce more than 1 Mtpy of aggregate and account for more than half of the total crushed stone production (Tepordei 2004). The uses of crushed stone are discussed in the Aggregates chapter in this volume.

The aggregate industry does not adhere to a scientific rock classification when describing or reporting production of crushed stone. For example, *limestone* commonly refers to limestone, dolomite, and marble. The coarse-crystalline igneous or metamorphic rocks, whether light colored (such as granite or gneiss) or dark colored (such as gabbro), commonly are referred to as *granite*. The term *traprock* is generally used to describe any fine-grained, dark-colored extrusive igneous rock such as diabase, basalt, or andesite. Following that terminology, limestone made up about 71% of crushed stone production for the year 2000. Granite comprises 15% of crushed stone. Traprock comprises 7%. Other miscellaneous stone, including sandstone and quartzite, account for the remaining 7% (Tepordei 2004).

Crushed stone production, expressed as a percentage of total aggregate production, varies from state to state, depending on a

Table 1. Crushed stone production for the year 2002 by state

State	Crushed Stone Value, \$1,000	Crushed Stone Production, kt	Crushed Stone as Percentage of Total Aggregate Production	State	Crushed Stone Value, \$1,000	Crushed Stone Production, kt	Crushed Stone as Percentage of Total Aggregate Production

variety of reasons including geology, availability, ease of obtaining permits, local or regional specifications, and operator preferences. Some 26 states produce more crushed stone than sand and gravel. In the United States in general, more crushed stone is produced than sand and gravel (Table 1).

The amount of foreign trade in crushed stone is minor. During 2002, about 2.6 Mt were exported, and about 14.3 Mt were imported. Most trade is with Canada and Mexico.

Total world production of aggregate (including crushed stone as well as sand and gravel) is estimated at 15 billion tpy. Production in the European Union is about 3 billion tpy, representing about two thirds of the European total (Regueiro et al. 2002). Aggregate production rates plummeted in Eastern Europe following the political reorganization of the early 1990s. More recently, production rates have stabilized, resulting in modest increases in demand in countries with emerging economies. Approximate production in other major aggregate-producing countries, in tons per year, is China, 4.5 billion; Japan, 550 million; Russia, 432 million; and Canada, 385 million (Regueiro et al. 2002).

Although crushed stone resources, like all nonrenewable resources, are finite, the potential supply of crushed stone resources on a worldwide scale is so large that "finite" is meaningless. But sources of crushed stone of suitable quality for an intended use can be in short or nonexistent supply on a regional or local scale

because of unfavorable geology, encroachment by incompatible land uses, and inability to obtain the necessary production permits.

A number of materials may be used as a substitute for crushed stone. The most widely used one is sand and gravel. Other common substitutes include recycled concrete or asphalt and slag. An expanded discussion of substitutes can be found in the Aggregates chapter in this volume.

GEOLOGIC ORIGIN AND DISTRIBUTION

Origin

Sedimentary rocks form by consolidation of loose sediment by biochemical, chemical, or mechanical processes. Biologically or chemically deposited carbonate sedimentary rocks form from the remains of living things, such as corals, clams, and other marine organisms that have the ability to secrete calcium carbonate, or they chemically precipitate directly from the water. Carbonate sedimentary rocks commonly used as crushed stone include limestone (calcium carbonate) and dolomite (calcium-magnesium carbonate).

Mechanically deposited (clastic) sedimentary rocks are classified according to the sizes of contained particles. Rock that consists mostly of pebbles and larger fragments is conglomerate; rock that consists mostly of sand-sized particles is sandstone; and rock that consists primarily of silt- or clay-sized particles is siltstone or shale, respectively. Of the clastic sedimentary rocks, hard and

dense sandstone, and to a much lesser amount siltstone and conglomerate, are commonly used for crushed stone.

Igneous rocks form from cooled magma and are classified by their origin and composition. Intrusive igneous rocks solidified at depths within the earth and developed large mineral crystals owing to the slow cooling associated with deep burial. Examples of extrusive igneous rocks with large crystals include granite (light colored) and gabbro (dark colored). Volcanic igneous rocks were extruded onto the earth's surface where they cooled and solidified relatively rapidly. Rapid cooling promoted the formation of only small or microscopic crystals. Examples include rhyolite (light colored) and basalt (dark colored). Many igneous rocks such as those mentioned are hard, tough, and dense, and make excellent crushed stone.

Metamorphic rocks form when existing rocks are subjected to heat and pressure within the earth. Metamorphic rocks that are hard, tough, and dense can be used as aggregate. These include gneiss, marble, hornfels, amphibolite, and quartzite. Some metamorphic rocks, such as highly foliated schist, have planar foliation caused by crystallization of parallel phyllosilicate minerals (micas). This foliation produces planes of weakness that are undesirable in crushed stone. In some parts of the Southwest, the Dakotas, and Wyoming, metamorphic rocks referred to as *clinker* are formed by the heat from in situ coal combustion. In some places clinker is used as aggregate.

Distribution of Major Rock Types

Limestone (using industry terminology) is widely distributed throughout the United States (Figure 1), although its suitability for crushed stone varies greatly. Limestone occurs in the mid-continent from the Great Plains eastward to the western flank of the Appalachian Mountains; the Coastal Plains of Florida, Mississippi, Alabama, Georgia, and South Carolina; the Balcones Escarpment in Texas; the Black Hills of South Dakota and Wyoming; the Great Plains in Kansas and Nebraska; all the western states, including the Rocky Mountains and areas to the west; Alaska; and Hawaii. During 2002, every state in the United States, except Delaware and New Hampshire, produced crushed limestone (Langer 1988).

Granite is widely distributed throughout the United States (Figure 2). It occurs in the Appalachian and Adirondack mountains, northern Minnesota and Wisconsin, the Black Hills of South Dakota and Wyoming, southeastern Missouri, central Arkansas, southern Oklahoma, central and southwestern Texas, all the western states including the Rocky Mountains and areas to the west, and Alaska (Langer 1988). During 2002, 35 states produced crushed granite.

Extensive amounts of traprock occur in the western United States from the eastern flanks of the Rocky Mountains to the west coast (Figure 3). In the eastern United States, traprock generally is restricted to the Triassic/Jurassic basins in the Appalachian Province, primarily in the Connecticut River valley of Connecticut and Massachusetts; the Palisades of New Jersey and New York; the Piedmont of Pennsylvania, Maryland, and northern Virginia; and in Georgia and Alabama (Langer 1988). During 2002, 24 states produced crushed traprock.

PROPERTIES

The properties of crushed stone result from the origin and mineralogy of the source rock and its subsequent alteration and weathering. Some important properties of a rock are the type, size, shape, orientation, and proportions of mineral grains; the type of contacts between the mineral grains; the layering of minerals; and the presence and interconnectedness of voids (Dolar-Mantuani 1983; Langer 2001b). These are all characteristics related to the origin

Figure 1. Generalized distribution of limestone in the conterminous United States

Figure 2. Generalized distribution of granite in the conterminous United States

Figure 3. Generalized distribution of traprock in the conterminous United States

and subsequent weathering or alteration of the rock and can be observed and described by traditional geologic methods.

The important properties of the minerals that comprise the rock are hardness and cleavage. Hardness of a mineral commonly is measured by geologists using the Mohs hardness scale, which

refers to the ability of one mineral to scratch the other. Cleavage is the ability of a mineral to break along a fixed crystal plane and varies from “perfect,” as illustrated by the mineral mica, to “none” as found in the mineral quartz.

The quality of crushed stone is most often defined by its conformance to specifications set by the user. Because most crushed stone is used in highway construction, those specifications commonly are set by state departments of transportation. Most states conform to the grading and testing standards set by the American Association of State Highway and Transportation Officials (AASHTO) or the American Society for Testing and Materials (ASTM). An expanded discussion of specifications and testing methods for crushed stone can be found in the Aggregates chapter in this volume.

Physical Properties

When crushed, the stone particles should be strong, which means they should resist abrasion; hard, which means they should resist loads; tough, which means they should resist impact; and sound, which means they should be able to withstand stresses caused by repeated freezing and thawing or wetting and drying (Langer and Knepper 1998; Langer 2001b).

Limestone and dolomite generally make good sources of crushed stone, although some limestone and dolomite may be soft, absorptive, and friable, which results in poor-quality aggregate. Typical compressive strengths for unweathered carbonate rocks range from 2,000 to 37,000 psi (Winkler 1973). The main factors responsible for strength of carbonate rocks are their interlocking grain fabric and their mineralogy. Strength of carbonate rocks generally increases over geologic time because of recrystallization and associated decreasing porosity. Consequently, geologically older carbonate rocks tend to be stronger than younger rocks (Bell 1993). Siliceous limestone and dolomite tend to have higher abrasion resistance than their nonsiliceous counterparts. The low hardness of minerals in younger limestone and dolomite give those rocks low abrasion resistance. Siliceous rocks such as chert have high resistance to abrasion.

Hard, well-cemented, or indurated, quartz-rich sandstone commonly makes an excellent source of crushed stone, although some sandstone may be soft, absorptive, and friable, which results in poor-quality aggregate. Typical compressive strengths for unweathered sandstone range from 5,000 to 36,000 psi (Winkler 1973). The main factors affecting the strength of clastic sedimentary rocks are porosity and the nature and amount of cementation of the grains. Development of mineral orientation in the sediments can result in planes of weakness in the rock. The abrasion resistance of sandstones largely depends on the nature of the cement between the grains.

Hard, tough, and dense, extrusive volcanic rocks commonly make an excellent crushed stone. Typical compressive strengths for unweathered basalt range from 16,000 to 49,000 psi (Winkler 1973). Some volcanic rocks may be unsuitable for aggregate if they are flow-banded, strongly jointed, vesicular, or brecciated. The presence of vesicles tends to reduce resistance to abrasion. If the vesicles are filled, the mineral content of infillings influences the resistance of rocks to abrasion. Pyroclastic volcanic materials such as ash and tuff may be unsuitable for some uses.

Intrusive igneous rocks commonly are hard and strong. Typical compressive strengths for unweathered granitic rocks range from 14,000 to 45,000 psi (Winkler 1973). The high strength results from mineralogy (large amounts of quartz and feldspars), small grain size, and intense grain intergrowth. The main factors that reduce the strength of igneous rocks are large crystal size, a high

proportion of soft minerals such as mica, and weathering or alteration. Weathering may increase the proportion of soft material and may result in destruction of intergranular bonding.

Metamorphic rocks commonly used as aggregate include gneiss, quartzite, and hornfels. These rocks tend to be hard and strong because of interlocking grains and low porosity. Granular quartzite and hornfels have a high abrasion resistance caused by their strong mineral contents. Quartzite is so tough that it commonly causes excessive wear on crushing equipment. The principal factors causing reduced strength of metamorphic rocks are increases in grain size, porosity, proportion of soft minerals, and, in particular, loss of intergranular bonding resulting from the development of strong mineral orientation (schistosity or foliation). Strong mineral orientation can also create a rock with high strength in one direction and low strength in another.

Properties of rock particles that affect soundness are the size, abundance, and continuity of pores, channels, and fractures, together with the degree of water saturation (McLaughlin et al. 1960). Porosity affects the strength and elastic characteristics of rock, and may affect permeability, absorption, and durability. It is generally accepted that there is an approximate inverse correlation between quality, as it pertains to soundness, and rock porosity. Rock with water absorption of 2% or less will usually produce good crushed stone, whereas otherwise suitable rocks with a water absorption that exceeds 4% may not (Smith and Collis 2001).

One of the most important physical properties of rock particles that affect freezing–thawing is the size of the pores. When water turns to ice, it increases in volume by about 9%, thus creating pressure within the pores of a stone. The critical pore size for freeze–thaw durability appears to be about 5 μm (Larsen and Cady 1969). Larger pore diameters allow drainage and escape of water from the frontal ice advance line.

Specific gravity is a general term used to express the relationship of the weight of a substance to the weight of an equal volume of water. Bulk specific gravity is the ratio of the weight of a given volume of material, including all voids, to the weight of an equal volume of water. Apparent specific gravity is the ratio of the weight of a given volume of material, including all impermeable voids, to the weight of an equal volume of water. High specific gravity generally indicates high-quality aggregate. Very low specific gravity frequently indicates aggregate that is porous, weak, or absorptive, although contractors generally favor the lightest stone that will pass specification, because in applications such as concrete or asphalt, aggregate is purchased by the ton while the final product is sold by the yard. Specific gravity of crushed stone is important in some applications that require heavyweight applications.

Other factors contributing to low soundness include the presence of weak, cleavable, absorptive, or swelling particles. Examples of low-soundness rocks include some shales, sandstones, limestones, clayey rocks, some very coarse crystalline rocks, and porous cherts (Neville 1973; Gillott 1980). Weathered rock types, such as weathered igneous rocks where secondary clay minerals are produced, can also be unsound (Fookes 1980). Because the physical properties of the rocks, not their composition, control frost susceptibility, not all the types of rocks mentioned have soundness problems.

Weathering and Impurities

Crushed stone should show no visible signs of weathering. Conduits in the bedrock provide for the passage of water, which in turn accelerates the weathering process. The presence of weathered bedrock increases the overall cost of separating suitable from unsuitable material and affects the blasting and extractive techniques used. The

rate and type of weathering depends on the climatic conditions, the geometry of the deposit, the relationship to the water table, and the properties of the rock. Weathering can range from slight discoloration, through the introduction of fractures and alteration of minerals, to complete decomposition and disintegration of the rock.

Chemical Properties

The chemical properties of crushed stone vary among rock types and are controlled by the mineralogy of the individual particles. Crushed stone generally is considered to be inert, but it may contain certain types of silica minerals that adversely react with the alkaline fluids in cement concrete and affect the life of concrete. Carbonate rock is soluble in weak acids. Certain zeolites release sodium and potassium, thus changing the pore water chemistry. Sulfides oxidize (rust), and salts dissolve or impede setting of concrete. The Aggregates, and Cement and Cement Raw Materials chapters in this volume contain expanded discussions of the physical and chemical properties of aggregates and how they affect their use.

CRUSHED STONE INDUSTRY

Crushed stone must physically be able to be mined and be accessible to transportation systems and to markets. The site must qualify for all necessary land use and environmental permits. The operation must be profitable, considering all costs, including acquisition, operation, compliance with regulations, and reclamation (Drye 1976; Banino 1994). These requirements make opening a new operation a complicated, risky process that involves substantial cost and can take many years.

Prospecting Techniques

The Stone Industries (Bowles 1939) is one of the first comprehensive publications on the stone industry that describes prospecting techniques for potential sources of crushed stone. Exploration for sources of crushed stone has become more than simply locating a source of suitable material and commonly is based on the principle of the "weakest point" (Dunn 1991). During exploration, a weakest point exists that should be analyzed before proceeding to other elements of exploration. For example, it may be unwise to intensely study a potential source of crushed stone in an area where fragmented land ownership makes a new operation highly unlikely. Conversely, it would be equally unwise to thoroughly address all permitting requirements before some estimate of the quality of the rock is determined. Thus, exploration requires judgment and experience and should proceed in a logical sequence. Each weak point should be resolved to an acceptable level of risk before proceeding to the next weakest point (Dunn 1991).

Assessing preliminary target areas for sources of crushed stone exploration should consider favorable geologic terrains as well as economic and social factors such as markets, transportation options, current land use, zoning regulations, and property ownership. Public hearings commonly are held before governmental bodies such as county or town boards, and the public and governmental views toward aggregate production must be carefully analyzed (Dunn 1991).

Exploration for potential sources of crushed stone within the target areas commonly begins with desktop studies utilizing existing data. Detailed geologic maps and cross-sections exist for large parts of the United States and elsewhere, and many of these can be used to help locate potential sources of crushed stone. Other sources of information include test holes and engineering tests of core from highway and other construction projects.

In areas where existing large-scale geologic information and other data are inadequate, or as a supplement to other information,

aerial photography (about 1:50,000 scale or larger), remote sensing (satellite or airborne spectral imagery), and airborne geophysical surveys may be useful for detecting and identifying bedrock outcrops (Knepper, Langer, and Miller 1995).

Preliminary field studies commonly are conducted to check the veracity of desktop analysis and to collect new data. Natural and synthetic exposures are investigated and sampled to determine variations in mineralogy, layering, fractures, weathering, and other rock properties. A geologist may also evaluate the site to identify potential environmental factors and to prepare plans for more detailed site evaluation.

If reconnaissance studies indicate a target area worthy of further investigation, the next steps are more detailed field studies. Acquisition of more detailed information increases costs, and it is appropriate to assess the weakest point at this stage of exploration. For example, economic and social factors, such as current land use, zoning regulations, and property ownership, as well as environmental factors, might be investigated in more detail, particularly because it will be necessary to obtain permission from landowners to access sites for further studies.

Systematic sampling must be conducted to determine the areal extent, thickness, stratigraphic variation, and physical properties of the rock. A variety of truck-mounted drills commonly are used to determine these factors as well as to obtain samples to determine the properties of the rock (Saint Don, Prueher, and Barnwell 2004). Core drilling is the most common type of exploration and should be of a size (after splitting) that allows for testing of the largest product to be mined. The core should be logged and split for testing. The remaining material should be archived as a permanent record.

The spacing of drill holes are site specific and should be based on the predictability and geologic continuity of critical characteristics of the deposit as determined by personnel specially trained in such procedures (Dunn 1991; Timmons 1994). Sample spacing depends on the desired level of detail and confidence of measurements, and typically ranges from 30 m in highly complicated areas to as much as 500 m in large areas of very simple geology. Sampling plans commonly are modified during site characterization based on knowledge gained during the sampling process.

Sedimentary and metamorphic rocks can be highly variable in quality and thickness. A single fault can trigger displacements and change the dips of beds. Many intrusive igneous rocks are difficult to characterize because of subtle changes in mineralogy and the presence of fault or fracture zones. Relatively flat-lying extrusive igneous and homogeneous sedimentary rocks sometimes can be characterized with less robust sampling. In dipping sedimentary rocks, drilling should be as close to perpendicular to the bedding as possible and should have some stratigraphic overlap between holes.

Test holes commonly are measured to determine the depth to the water table. Other observation wells may also be drilled to monitor groundwater conditions.

Seismic geophysical methods have been applied to the investigation of stone resources for more than 65 years (Patterson 1937). Those techniques, as well as other properly conducted surface geophysical surveys, can provide information on the thickness of overburden and can be used to help locate drill holes, provide continuity between drill holes, locate large openings in bedrock, and identify major changes in bedrock types. The surveys can be run in areas where rapid geological changes might be undetected by drilling such as areas of suspected fault zones, areas of steeply dipping bedrock, and areas of other elusive, but important, geologic conditions. The locations and results of the geophysical surveys commonly are included on the geologic maps and accompanying reports prepared for potential crushed stone operation sites.

Table 2. Specific gravities of selected common rocks

Rock Type	Specific Gravity	Rock Type	Specific Gravity
Andesite	2.4 to 2.8	Granite	2.6 to 2.8
Basalt	2.7 to 3.2	Limestone	1.9 to 2.8
Dolomite	2.7 to 2.8	Marble	2.6 to 2.9
Gabbro	2.9 to 3.1	Sandstone	2.0 to 3.2

Source: Adapted from Dunn 1991 and Marek 1991.

Five methods of geophysical surveys can be used to evaluate bedrock sources of crushed stone: seismic, radar, gravity, magnetic, and electrical. None of these techniques is particularly useful for characterizing rocks. They do have engineering applications, however, that can be applied to quarrying. Seismic studies can be used to estimate rippability of stone, to identify weathering zones, and to locate the water table. Radar is routinely used to detect voids and may have application in cavernous limestone areas. Gravity can be used for a qualitative estimate of cavities, joints, or other discontinuities of highly contrasting bedrock. Most rocks considered for use as aggregate do not contain magnetic minerals, but if they do, magnetic surveys may prove useful. Electrical surveys may help identify changes in water content or in some situations identify electrical properties of some rocks.

An experienced field geologist can determine whether or not a geophysical survey is warranted and which methods should be used. The spacing of geophysical survey patterns are site specific and should be based on geologic characteristics of the site and the predictability of continuity of the deposit's critical characteristics as determined by personnel specially trained in such procedures (Dunn 1991; Timmons 1994). Survey plans commonly are modified during site characterization based on knowledge gained during the sampling process.

The results of geophysical surveys are limited because it is not possible to translate geophysical data without correlative evidence normally provided by borings. In addition, geophysical surveys generally provide a very broad guide to the site characteristics and must be refined by other means. Actual subsurface information is desirable so that geophysicists have an idea of how to interpret the results of the surveys.

The geology of a potential crushed stone source must be sufficiently known so that all critical variations in the characteristics of the bedrock and overburden are understood. Geologic mapping is a way of systematizing field observations and is a valuable tool for planning drilling and sampling locations (Dunn 1991), assessing geophysical needs, establishing background data, and identifying potential environmental impacts associated with aggregate development. Geologic maps, accompanying cross sections, and geologic reports of potential sources of crushed stone vary depending on the rock type, but commonly show the location and outline of the rock, the location of sampling sites and geophysical surveys, measurements of the thickness and attitude of rock units, and descriptions of rock properties at depth. Supplemental maps and reports can also describe related issues such as the thickness of overburden, altitude of the water table, geologic hazards, and so forth. In many states, such reports must be prepared by a licensed professional geologist.

The difficulty of calculating volumes of deposits has been greatly eased with the use of specialized mining and quarrying software, geographic information systems (GISs), and computer-aided design (CAD) software. Usable volumes exclude areas of setbacks, access roads and other infrastructure, maintenance facilities, and so

forth. Information obtained during geologic mapping and sampling can be entered directly into these programs, and the programs can calculate resource volumes using various algorithms.

Regardless of how volumes are determined, the *in situ tonnage* of rock is calculated by multiplying the weight of rock per unit volume by the estimated volume. If the weight of the rock is expressed as specific gravity (Table 2), the weight of rock per unit volume can be calculated by multiplying the specific gravity by the weight of water per unit volume. For example: the unit weight of water is 62.4 lb/ft³ (1 t/m³). Assume the specific gravity of basalt is 3.0. The unit weight of basalt is $(62.4 \text{ lb/ft}^3 \times 3.0) = 187.2 \text{ lb/ft}^3$.

The *usable tonnage* of rock is the *in situ tonnage* less the uncoveredable material from waste rock, buffer zones, quarry slopes, haul roads, facility sites, and so forth.

There are numerous methods for appraising crushed stone quarries depending on the purpose of the appraisal and the status of the quarry (Evans 1995; Paschall 1998), but for industrial minerals such as crushed stone, economic and legal issues may be as important as the geologic aspects of a deposit. Companies perform detailed reserve estimates and appraisals for a variety of reasons, including sale or purchase of undeveloped resources or reserves, acquisitions and mergers, valuation of a mining property, accounting, financing, taxation, condemnation, mineral conservation, and for internal planning. Customers can precipitate an analysis of reserves by demanding proof of the existence and quality of reserves before committing to long-term purchase agreements.

Mining

Site preparation commonly starts with grubbing followed by stripping of sufficient overburden to access the resource. Topsoil commonly is separated from the overburden and stockpiled for reclamation activities. Overburden may also be used to construct berms or to be stockpiled or sold. Soil or overburden should not be stockpiled where future extraction is expected, and the final need for reclamation should be considered. Site preparation also includes construction of access roads, fences, berms, haul roads, drainage ditches, culverts, settlement ponds, processing and maintenance facilities, and other plant infrastructure. Quarrying commonly progresses downward on several different levels or "benches," which are formed by drilling, blasting, and excavating rock.

The technology of rock blasting is highly developed. Holes are drilled into the rock and are partially filled with explosives. The top portion of the hole is filled with nonexplosive material (usually sand or crushed stone, sometimes separated from the explosives with a manufactured plug) that is referred to as *stemming*. The explosive in each hole is initiated with detonators or blasting caps. Digital timing, detonator design, or other technology creates delay periods between blasts in individual holes. The total blast commonly lasts only a fraction of a second and consists of many smaller individual blasts separated by delays of a few thousandths of a second. When the explosive is detonated, large volumes of gases are instantly produced, fracturing the rock. The stemming material keeps the expanding gases in the rock in order to maximize the effect. The delay periods between charges ensure that each hole will have to break only the rock immediately in front of it. For example, if two rows of blast holes are parallel to the quarry face, the front row of holes will be detonated first, fracturing and displacing that rock. The back row of holes will then be detonated and will not have to break the rock already displaced by the first round of blasts. In addition, each single blast hole in each row of holes will be detonated separately to reduce ground vibrations from the blast, which may be important when the quarry is near structures.

After the rock is blasted, it is loaded onto trucks or conveyors using conventional earth-moving equipment such as front loaders and track hoes. The blasted material is then transported to the processing facility.

Processing

Processing may be as simple as a portable crusher and screens or can be a highly automated, sophisticated procedure. There are numerous ways to configure equipment, depending on the characteristics of the rock being crushed and its final use. Figure 4 is a flow diagram showing the generalized processing steps.

Rock rubble from the quarry face is dumped into a primary crusher where the large rock fragments are broken into smaller sizes. In some operations, the rubble goes over a large screen (referred to as a “grizzly”) located before the primary crusher. Large material, referred to as the “overs,” is rejected by the grizzly, and smaller material, referred to as “throughs,” goes into the crusher. In other operations, large material is selectively avoided by the loader operator, and the grizzly is located after the primary crusher. The overs are either put back into the primary crusher and broken into smaller pieces, or they are set aside for sale as riprap or armor stone.

The material that comes out of the crusher is moved by a conveyor to a surge pile. A gate at the bottom of the surge pile releases the rock rubble at a constant feed rate to a secondary crusher where it is broken into smaller sizes. Crushing to the proper size usually occurs in stages, because rapid size reduction, accomplished by applying large forces, commonly results in the production of excessive fines (Rollings and Rollings 1996). The crushed stone is screened to sort into size ranges. Particles that are too large go back through the crushing and screening process. After crushing, the material may be washed to remove fines, depending on the type of material being processed and on the final product. After screening, sorting, and washing (if necessary), conveyors move the material to stockpiles.

Procedures must be followed carefully for stockpiling and handling the final product. The processing of aggregate resources requires significant effort and cost to prepare a product that meets exacting specifications regarding grading, freedom from contaminants, and other requirements. Mishandling of aggregate can result in significant degradation of the product (Rollings and Rollings 1996). When aggregate falls from conveyors onto coned stockpiles, when it is dumped from trucks down a slope, or when equipment pushes it over long distances, the material can separate from a well-blended product into individual sizes. Improper handling can also result in contamination of the aggregate with foreign material from underneath the stockpile.

Depending on the crushing and screening process, stockpiled material may consist of a single size of rock clasts or a range of particle sizes. For example, the crushing and screening can be designed to produce a well-graded base course material that ranges from coarse to fine particles, or to produce a single-sized product such as 4 to 2 cm stone. See the chapter on aggregates in this volume for a discussion on transportation, marketing, and uses of crushed stone.

REGULATORY AND ENVIRONMENTAL CONSIDERATIONS

Regulations

Crushed stone quarrying is permitted or controlled at the federal, state, and local levels of government by numerous governmental agencies. All states are subject to federal law, whether land within state boundaries is federal, state, or privately owned. Indian tribal lands are considered sovereign and are subject to federal law, but without state jurisdiction or taxation.

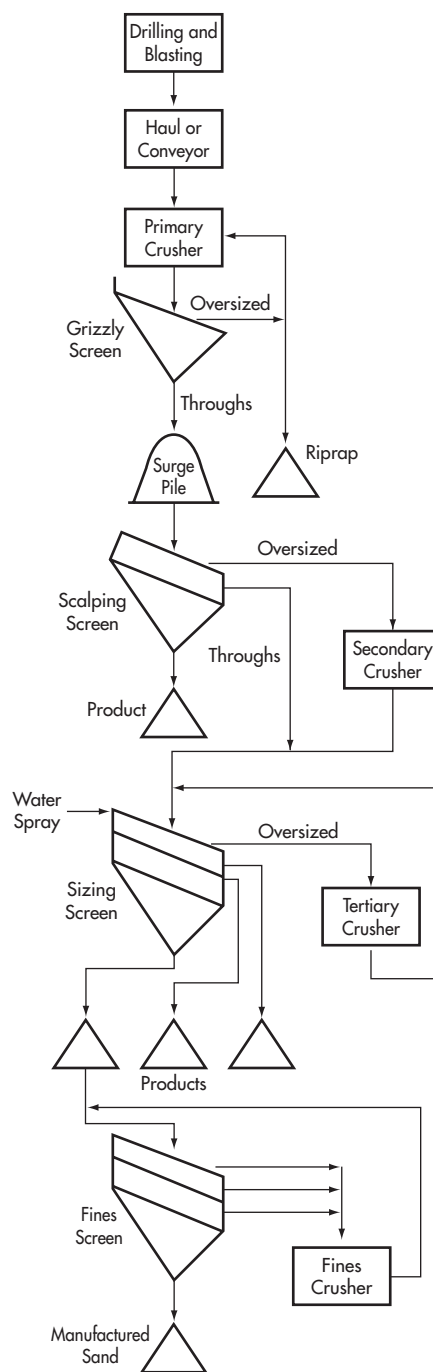

Figure 4. Diagram of crushed stone processing

Approximately one third of all land in the United States, most of it in the westernmost conterminous states and Alaska, is owned by the federal government. The agencies managing most of those lands are:

- Bureau of Indian Affairs
- Bureau of Land Management
- Bureau of Reclamation
- National Park Service

- U.S. Army Corps of Engineers
- U.S. Fish and Wildlife Service
- U.S. Forest Service

The General Mining Act of 1872 encouraged exploration of federal lands for mineral resources, including common minerals. In 1955 Congress removed common construction materials (termed "saleable minerals," including crushed stone) from the mining law and made them available through a contract or bidding process at the discretion of the land management agency (Arbogast 2002).

The Water Quality Act of 1965 and the Federal Water Pollution Control Act Amendments of 1972 (retitled the Clean Water Act) were enacted to provide efficient water pollution control. Every major point source (a confined conveyance such as a pipe, drain, or ditch) from which pollution is discharged into U.S. waters requires a joint federal-state permit (Arbogast 2002). Crushed stone quarrying activities that are covered include quarry runoff and discharges from settlement ponds and quarry dewatering.

The Air Quality Act of 1967 (amended by the Clean Air Act Amendments of 1970) gives states and local governments the responsibility to develop and implement plans to address airborne pollution at its source. Crushed stone quarrying activities that are covered include dust and exhaust emissions (Arbogast 2002).

Other federal regulations indirectly control the production of aggregate resources through numerous acts, including the Fish and Wildlife Resource Management Act, the Fish and Wildlife Coordination Act, the Migratory Bird Treaty Act, the Endangered Species Act (including the Rivers and Harbors Act), the Coastal Zone Management Act, and the National Environmental Policy Act. The operation of crushed stone quarrying is controlled at the federal level by the Mine Safety and Health Administration (MSHA).

Each of the 50 states has a different process for obtaining permission to extract minerals. Some states issue permits for aggregate mining; others leave that authority with local agencies. The result is inconsistent policies among states and between the states and federal agencies. Commonly, state agencies enforce federal regulations such as air quality, water quality, diversion or impoundment of surface water, withdrawal of groundwater, and water quality.

In a review of various state mining laws, Arbogast (2002) found that at least 37 states regulate non-coal surface mining on a statewide basis. Thirty-five states require some sort of bond or security from the operator. At least 26 states provide for public comment at permit review. Some states have no legislation to regulate crushed stone quarrying. In some states, crushed stone quarrying is regulated at the local level.

Through the Standard State Zoning Enabling Act of 1922, the federal government encouraged state and local governments to create zoning codes. The authority of governments to enforce zoning regulations was upheld by the Supreme Court in 1926 in the landmark case of *Village of Euclid, Ohio v. Ambler Realty*. Since then, every state has enacted zoning legislation. Many, but not all, states transfer zoning authority to county or municipal authorities. Some rural areas in the United States, however, remain unzoned.

The United States is made up of more than 3,000 counties and many more local governmental authorities. Counties and other local governments may or may not have final permitting authority for crushed stone quarrying. Even where local governments do not have this authority, they commonly influence the final land-use decision by controlling land-use activities such as ground disturbance, grading, noise, traffic, aesthetics, storm water, erosion and sedimentation, land use, building codes, hours of operation, and regulation of utilities. Approval of crushed stone quarrying is frequently contingent on these issues (Arbogast 2002).

Environmental Considerations

Two reference documents dedicated to the aggregate industry that address environmental impacts from aggregate mining are by Barksdale (1991) and Smith and Collis (2001). Five comprehensive collections of individual papers that describe many issues related to aggregate development are by the International Association of Engineering Geology (1984); Kelk (1992); Lüttig (1994); Bobrowsky (1998); and Kuntz, Väisänen, and Uusinoka (2001). This information on the environmental impacts of aggregate mining, plus references from other journals, is summarized by Langer (2001a) and Langer, Drew, and Sachs (2004). A study of reports in these papers provides an understanding of the many different environmental impacts related to aggregate mining and gives a historical perspective of the issues.

Potential environmental impacts—such as visual changes, noise, dust, runoff, sedimentation, and impacts to groundwater and surface water—may occur with any type of aggregate operation. Most environmental impacts associated with crushed stone operations are relatively benign because aggregates are environmentally inert materials and their processing commonly does not involve the use of hazardous chemicals. Furthermore, environmentally sound and safe aggregate operations effectively manage physical disturbances, protect ground- and surface waters, control noise and dust, use safe blasting procedures, and have long-term operation and closure plans that recognize habitat and community needs.

Some of the most frequent concerns associated with crushed stone operations are the noise, dust, and ground vibrations associated with blasting, which may be daily or as infrequently as once or twice a year. A small amount of energy from a blast is released as vibrations through and along the surface of the earth and through the air. Extensive research by the former U.S. Bureau of Mines resulted in ground vibration standards that have become industry standards for safe blasting. Levels of ground vibration from blasting for residential structures that can limit damage to the type that develops in all homes, independent of blasting, range from 0.5 to 1.0 in./sec (1.27 to 2.54 cm/sec) peak particle velocity (Stagg et al. 1984). Some energy from a quarry blast escapes into the atmosphere and causes audible noise as well as subaudible airblast, which is also referred to as air concussion. Airblast is most noticeable within a structure, particularly when windows and doors are closed, and frequently is mistaken as ground vibrations. U.S. Bureau of Mines research demonstrated that airblasts with an intensity of 134 dB (2 Hz) produce wall vibrations equivalent to that from a 0.5-in./sec (1.27-cm/sec) ground vibration (Siskind et al. 1980). Airblasts are less likely to crack walls than ground vibration because of the differences between the mechanics of vibrations from airblasts versus those from ground shaking.

Blast design parameters, which include maximum instantaneous charge; delay timing; hole diameter, spacing, and orientation; amount and type of stemming; and burden (the material between the face of the quarry and the first row of blast holes) can be altered to limit levels of ground vibration and airblast. Alternative rock-breaking techniques, such as ripping with heavy equipment or hydraulic fracturing, can be considered. Blasting times can be scheduled to coincide with periods of high activity rather than when people are relaxing in their homes.

Reclamation

The primary goal of reclamation is to return the land to a beneficial second use. Reclaimed pits or quarries have been converted to diverse uses, including lakefront property, recreational areas, wildlife areas, botanic gardens, golf courses, agricultural areas,

industrial and commercial properties, office parks, and landfills. Reclamation frequently is planned before mining begins, although less often with crushed stone operations than with sand and gravel operations because of the long period of time between opening and closing of stone quarries. Arbogast, Krepper, and Langer (2000) describe many reclamation options.

OUTLOOK AND FUTURE TRENDS

The U.S. Geological Survey (USGS) calculates future crushed stone production using a conservative value of 1.0% increase per year. At this rate, crushed stone production would be nearly 2 billion tpy by 2025. The USGS anticipates an increasing gap between crushed stone and sand and gravel production with a move toward crushed stone (Tepordei 1997).

Over the last few decades, the process to permit new crushed stone reserves has become increasingly difficult, lengthy, and expensive. Regulations, more than actual resource availability, restrict development or expansion of aggregate operations in established areas (Poulin, Pakalnis, and Sindig 1994). This trend, fueled by increased citizen opposition to disruptive land-use practices, is likely to continue.

The industry trend is toward large businesses with large operations and large output. Acquisitions of such businesses are expected to continue, especially as a means to obtain their permitted reserves. Increased costs, combined with local opposition to aggregate operations in populated areas, will likely force the location of new operations into more remote localities. Large centralized plants may take greater advantage of rail, barge, or freighter transport and will service one or more urban distribution centers. The automation of processing plants and bulk material handling systems will allow for higher production rates at reduced costs.

Imports of crushed stone from coastal Canada and Mexico to Atlantic, Pacific, and Gulf coastal ports are likely to increase, but with strong environmental controls to offset the concern of exporting environmental problems from the United States to Canada and Mexico.

Integrated software for permitting, reserve calculations, mine design, mine operation, blast-hole designs, blasting seismic records, stockpile management, scalehouse operations, and reclamation have become available at reasonable costs. Machine guidance systems are available that use global positioning satellites to determine the position of excavating equipment with centimeter-level accuracy.

Naturally occurring asbestos in mineral deposits, including some types of crushed stone, and the release of asbestos fibers into the air are potential environmental health concerns that face the crushed stone industry (Bailey 2004). Issues relevant to the industry are how to identify, measure, and prevent exposure to asbestos-form minerals. Crystalline silica is another potential environmental health issue that the aggregate industry faces, especially in crushed stone. Possible measures to address these issues, in addition to dust control, include employee training on asbestos and silica hazards, periodic medical exams of potentially exposed workers, and exposure monitoring (Bailey and Sharpe 2003).

There is a slow but inexorable move toward implementation of sustainable resource management principles (Langer, Guisti, and Barelli 2003) and best management practices by sand and gravel producers, particularly by large U.S. and multinational companies. Sustainable aggregate resource management can be achieved in a practical sense by adopting the following simple principles (after Plant and Haslam 1999).

Planning, project design, approvals assessment, and site conditions should

- Maximize the economic value of the resource: by extracting as much material as possible from the disturbed area and for the most economically valuable use it can accommodate
- Minimize waste of the resource: by avoiding high grading (picking the best parts of the resource and spoiling the ability to extract the remainder) and by finding uses and markets for all of the disturbed material (e.g., turning crusher fines into “manufactured sand,” thus reducing the need for natural sand sources in more environmentally sensitive areas; and blending of lower-quality with higher-quality material while meeting product specifications)
- Minimize social and environmental impacts: by planning to protect important resources from urban encroachment and protect growing communities from the nuisance impacts of poorly designed, poorly located, and poorly managed aggregate operations; by using best-practice designs and operations to control the effects of blasting, noise, dust, sediment erosion, and visual scarring in extractive and transport operations; and by providing for conservation of natural values by management of buffer areas that maintain or enhance vegetation, wildlife habitats, and corridors
- Maximize rehabilitation of disturbed areas: by allowing for reclamation as part of the quarry/pit design process before extraction begins; by starting rehabilitation from Day One; and by being flexible enough to allow for advances in technology and for changing local needs
- Maximize community engagement: by involving the local community in planning activities through open visit days and community awareness and educational activities (this may lead to a measure of community acceptance and a “social license to operate,” which can be just as important as the official, legal permits)

Lightweight Aggregates

Alfred L. Bush, Dennis P. Bryan, and Daniel R. Hack

INTRODUCTION

Lightweight aggregates are those minerals, natural rock materials, products, and by-products of manufacturing processes used as bulk fillers in lightweight structural concrete, concrete masonry units, precast concrete structural products, road-surfacing materials, plaster aggregates, and insulating fill. Other uses include architectural wall covers, suspended ceilings, lightweight structural fill, soil conditioners, and other agricultural uses (Mason 1994).

Separate commodity chapters elsewhere in this volume discuss aggregates in general, as well as individual commodities that comprise lightweight aggregates, such as common clays and shale, crushed stone, perlite, pumice, scoria, vermiculite, and volcanic cinders. In addition, Chandra and Berndtson (2003) is an excellent reference book on this topic.

LIGHTWEIGHT AGGREGATE TYPES

Most lightweight aggregates are mineral raw materials; the remainder are waste or synthetic products (Mason 1994). Lightweight aggregate materials are generally classified into four groups:

1. Natural lightweight aggregate materials—prepared by crushing and sizing natural rock materials such as pumice, scoria, tuff, breccia, and volcanic cinders.
2. Manufactured structural lightweight aggregates—prepared by pyroprocessing shale, clay, or slate in rotary kilns or on traveling grate sintering machines.
3. By-product lightweight aggregates—prepared by crushing and sizing foamed and granulated slag, organic cinders, and coke breeze. Other by-product lightweight aggregates in use include coal combustion by-products (fly ash and bottom ash), flue gas desulfurization by-products resulting from manufacturing processes, or other waste products. This group, with the exception of slag, has continued to decline in popularity and is not discussed here.
4. Manufactured insulating ultra-lightweight aggregates—prepared by pyroprocessing ground vermiculite and perlite (Mason 1994).

This chapter covers the use of both natural lightweight aggregates and manufactured insulating ultra-lightweight aggregates and focuses on the production and use of manufactured structural lightweight aggregates. Organic products such as rice hulls, straw, and peat have been used as lightweight aggregate, but they are quantitatively insignificant and are not discussed here.

STRUCTURAL LIGHTWEIGHT AGGREGATES

Lightweight aggregates—both natural and manufactured, and suitable for structural uses—should have low bulk density yet suitable strength characteristics to pass on to the end product. For the most part these end uses are concrete products such as portland cement concrete or concrete masonry units, both of which are used extensively in structures of various kinds. Heat treatment usually results in relatively thick pore walls (compared to void diameter) that give the aggregates suitable compressive strengths. The porosity of all these aggregates results from heat treatment, either naturally or artificially induced. A porous but relatively impermeable texture not only makes these materials lightweight but also makes them both thermal and acoustic insulators, desirable for bulk use in floor and roof fill and with an added advantage of saving weight in concrete (Bush 2001).

Higher strength and increased weight go together. Compressive strength, for example, ranges from about 1,200 psi (8.3×10^6 Pa) for 60 lb/ft³ (960 kg/m³) pumice aggregate concrete to more than 6,000 psi (42×10^6 Pa) for 120 lb/ft³ (1,920 kg/m³) expanded (sintered) shale concrete. In this broad range, lightweight aggregate concretes can be used for bridge decks; concrete walls and floors; concrete frames using precast, prestressed, or post-tensioned girders; precast tilt-up panels; poured barge and ship hulls; and lightweight concrete masonry units. In bulk form, the aggregates are also sometimes used as railroad ballast, as highway and embankment fill, and in the surface course of bituminous paving mixtures (Bush 2001).

The distinction between normal-weight and lightweight aggregates is about 75 lb/ft³ (1,200 kg/m³) for loose-graded coarse aggregate (between approximately ¾ in. and #4 sieve size). Most lightweight aggregates used for structural purposes are in the range of 35 to 60 lb/ft³ (560 to 960 kg/m³); those used for nonload-bearing purposes (ultra-lightweight aggregates) are in the range of 5 to 20 lb/ft³ (80 to 320 kg/m³). In contrast, most normal-weight aggregates such as crushed stone, and sand and gravel, are in the range of 70 to 110 lb/ft³ (1,150 to 1,700 kg/m³) (Bush 2001). Low-density lightweight aggregates are used primarily for insulation, and they have relatively low compressive strength. The middle-density aggregates are used for insulation and for fill. Those at the upper end develop excellent compressive strength and are used in many structural applications (Mason 1994). Dry weights for various lightweight aggregates are given in Table 1.

Table 1. Dry weights for various lightweight aggregates

Aggregate Type and Size Designation	Dry Loose Weight, maximum, kg/m ³ (lb/ft ³)
Structural lightweight aggregate	
Fine aggregate, 4.75 mm (No. 4) to 0	1,120 (70)
Coarse aggregate, 9.75 to 2.36 mm (3/8 in. to No.8)	880 (55)
Combined fine and coarse aggregate	1,040 (65)
Vermiculite	160 (10)
Perlite	196 (12)

Table 2. Grading requirements for lightweight aggregates (in percentages, by weight, passing sieves with square openings)*

Size Designation	25.0 mm	19.0 mm	12.5 mm	9.5 mm	4.75 mm	2.36 mm	1.18 mm	0.29 mm	0.149 mm
Lightweight Aggregates for Structural Concrete (ASTM C330-04)									
Fine aggregate									
4.75 to 0 mm				100	85–100		40–80	10–35	5–25
Coarse aggregate									
25.0 to 4.75 mm	95–100		25–60		0–10				
19.0 to 4.75 mm	100	90–100		10–50	0–15				
12.5 to 4.75 mm		100	90–100	40–80	0–20	0–10			
9.5 to 2.36 mm			100	80–100	5–40	0–20	0–10		
Combined fine and coarse aggregate									
12.5 to 0 mm		100	95–100		50–80			5–20	2–15
9.5 to 0 mm			100	90–100	65–90	35–65		10–25	5–15
Lightweight Aggregates for Concrete Masonry Units (ASTM C331-04)									
Fine aggregate									
4.75 to 0 mm				100	85–100		40–80	10–35	5–25
Coarse aggregate									
12.5 to 4.75 mm		100	90–100	40–80	0–20	0–10			
9.5 to 2.36 mm			100	80–100	5–40	0–20	0–10		
Combined fine and coarse aggregate									
12.5 to 0 mm		100	95–100		50–80			5–20	2–15
9.5 to 0 mm			100	90–100	65–90	35–65		10–25	5–15

* Blank spaces in this table indicate no specification given for this size range.

Most structural lightweight aggregate can make concrete weighing from 100 lb/ft³ (1,575 kg/m³) to 125 lb/ft³ (2,000 kg/m³). Exfoliated vermiculite and expanded perlite are sometimes referred to as *super* or *ultra-lightweights*. Insulating concrete (nonload-bearing) weighing as little as 15 lb/ft³ (240 kg/m³) can be made with these aggregates.

The principal properties desired in materials used as lightweight aggregates vary according to end use, but normally include the following (Mason 1994):

- Light weight—reduces dead load (weight in place) and facilitates the physical handling of the materials
- Strength—maintains the structural integrity of the end product, such as in concrete products
- Thermal and acoustical properties—normally the result of air spaces, voids, or pores in the lightweight aggregate materials
- High fire resistance—low probability of physical breakdown at temperatures below the melting point of the aggregate
- Toughness—minimum tendency to crack or break if nailed or stressed in construction use

Other properties that are sometimes considered desirable, depending on the application, include the following:

- Low water absorption
- Resistance to freezing and thawing
- Low shrinkage characteristics and minimum thermal expansion

- Good bonding with cement
- Chemical inertness
- Good elastic properties
- Abrasion resistance

The actual specifications and tolerances vary according to the end use or final product in which the lightweight aggregate is consumed. The American Society for Testing and Materials (ASTM) compiles specifications for various lightweight aggregate materials by use and standards can be consulted as required. Grading requirements for lightweight aggregates, based on ASTM C 330-04 and ASTM C 331-04, are given in Table 2. Grading requirements for lightweight aggregates for insulating concrete, based on ASTM C332-99, are given in Table 3. ASTM standards C330-04 (*Standard Specification for Lightweight Aggregates for Structural Concrete*), C331-04 (*Standard Specification for Lightweight Aggregates for Concrete Masonry Units*), and C332-99 (*Standard Specification for Lightweight Aggregates for Insulating Concrete*) are the most relevant for most lightweight aggregate materials (Mason 1994; J.P. Ries, personal communication). In addition, an ASTM special publication (Klieger and Lamond 1994) covers the significance of tests and properties of concrete-making materials.

Natural lightweight aggregates are mostly bulky, have low unit value, and normally serve local and regional markets. Some structural lightweight aggregates, however, are economically

Table 3. Grading requirements for lightweight aggregates for insulating concrete (ASTM C332-99) (in percentages, by weight, passing sieves with square openings)[†]

Size Designation	19.0 mm	12.5 mm	9.5 mm	4.75 mm	2.36 mm	1.18 mm	600 µm	600 µm	600 µm

shipped long distances because the density of these aggregates are one half to one third the density of locally available normal-weight aggregates such as crushed stone, sand, and gravel, and any comparison between lightweight and normal-weight aggregates should be made on a volume basis. For example, lightweight aggregate may be four times as expensive per ton as local normal-weight aggregate but can yield two to three times its volume. One ton of lightweight aggregate will normally make two to three times as much concrete end product as 1 t of normal-weight aggregate.

Products such as pumice or expanded slag may be used in substantial quantities in some localities and may not even be available (at competitive prices) in others. Perlite and vermiculite depos-

its are limited in location but serve national markets because of their relatively high market value and because their ores are shipped before pyroprocessing and physical expansion. Most pyroprocessing and expansion plants reflect specialty uses in regional and national markets. The more specialized uses command higher market prices that lead to extensive geographic distribution and use (Mason 1994).

Table 4 summarizes the annual output of lightweight aggregate in the United States for the period 1990 to 2002 by quantity, and Table 5 summarizes the stated values of lightweight aggregate production for the same period. Note that there is a qualification on the data for vermiculite (see the section on expanded vermiculite

Table 5. Value of domestic lightweight aggregate production, 1990–2002 (values in thousands of 1996 dollars, 1990–1998; in millions of dollars, 1999–2002; italicized values are unit price per metric ton)

under Ultra-Lightweight Aggregates in this chapter). Table 6 contrasts the average unit value of lightweight aggregate materials at production plants in 1990 and 2002. In recent years, significant price increases for expanded perlite and exfoliated vermiculite gave them a large share of the market in terms of value (approximately 32% in 2002) despite contributing only about 5% of the tonnage. Expanded shale, clay, and slate are widely used. In 2002 they accounted for about 39% of the total quantity and 27% of the value.

NATURAL LIGHTWEIGHT AGGREGATES

The “classic” types of natural lightweight aggregates are pumice and volcanic cinder. Aggregate for lightweight concrete is produced by mining, crushing, and screening to appropriate size. Other types of natural lightweight aggregates are also volcanic rocks such as tuffs, breccias, or pumiceous rhyolites and are found in recent volcanic terranes throughout the western United States.

Some lightweight material in use may be a manufactured product derived from an ore or raw material that is a natural mineral resource. For example, raw materials for lightweight aggregates can be iron ore and flux stone (the components of blast furnace slag); coal (the raw material from which cinders are derived); and shale, clay, and slate (which expand at elevated temperatures; Mason 1994). Even though these may originate as natural products, because heating results in dramatic physical changes, they are considered a manufactured lightweight aggregate.

Various volcanic rocks worldwide are suitable for use as lightweight aggregates; all are extrusive ejecta that range in composition from mafic to silicic. Scoria and volcanic cinder (both mafic) and pumice (silicic) make moderate-to-low strength structural aggregates; expanded perlite is an ultra-lightweight material. Water content in basalt is little different from that in scoria and cinder, but the difference between water in rhyolite and that in silicic glassy rocks is significant. An excess of water allows perlite to be thermally expanded. In a general way, viscosity of extruded rock melt varies directly with the SiO₂, Na₂O, and K₂O content and inversely with the Fe₂O₃, FeO, CaO, and MgO content; the mafic rocks are more fluid and the silicic rocks are more likely to retain gases.

Pumice

Pumice is used both as structural lightweight aggregate and sometimes as ultra-lightweight aggregate. It is lighter colored, of lower density, and more highly cellular than scoria and cinder. Naturally

occurring lightweight aggregate raw materials such as pumice and volcanic cinders are normally mined by open-pit or quarry methods, depending on the degree of consolidation of the raw materials. Mining costs are similar to those for sand and gravel except where substantial blasting and crushing are required. In the latter case, production costs parallel those for crushed stone (Mason 1994). Pumicite, a fine, glassy volcanic ash that historically has been used for similar applications as pumice, is usually discussed as part of the pumice family in the literature. It has not, to the authors' knowledge, been used to any extent as a lightweight aggregate in construction applications and therefore is not discussed here.

Pumice selling prices are approximately two to three times those of sand, gravel, and crushed stone, and have ranged from \$9.35/t (1986) to \$20.71/t (2002). A 20-city average price for gravel and crushed stone (19×9.5 mm) is \$9.68/t and \$6.88/t, respectively, as reported in December 2003 (*Engineering News-Record* 2003). Prices for domestic output of pumice for 1990 through 1997 ranged from \$22.60/t (1991) to \$30.98/t (1992) and averaged \$25.66/t. From 1998 through 2002, prices ranged from \$16.30/t (1998) to \$21.44/t (2001) and averaged \$19.50/t; for the entire 14-year period, the average was \$22.32/t.

Domestic output of pumice has increased steadily in recent years, from a low of 356 kt in 1987 to a high of 1,050 kt in 2000. It has hovered in the 900- to 1,000-kt range since 1999.

Pumice occurs throughout the western United States from the Rocky Mountains to the Pacific Ocean. Domestic producers increased in number from 8 in 1990 to nearly double that by 2000; and in 2002, at least 15 mines were operated in the United States, with Oregon being the leading pumice producer, followed by Arizona, New Mexico, California, and Idaho. Bulk densities range from 500 kg/m³ for pumice to 1,040 kg/m³ for pumicite.

U.S. production of pumice (sold or used) fell in 2003 because of decreased demand from the abrasives, building block, horticultural, and landscaping markets. The amount of pumice sold for building block decreased by about 10%, from 730,000 t to 654,000 t. The only major market that had increased sales was for concrete admixture and aggregate, which nearly doubled from 24,000 t to 42,000 t in 2002. The most important market for pumice remained building block, which consumed about 76.4% of the total domestically produced pumice sold or used in the United States. The average prices reported for pumice varied greatly by use. The overall average price was \$25.20/t in 2002, an increase of \$4.51/t (from \$20.69/t) in 2001. The price change was the result of a significant increase in the average price reported for the grades of pumice used in abrasives, and smaller increases in the prices for building block, horticulture, and landscaping. Average prices were \$312/t for abrasives; \$39/t for miscellaneous uses; \$27/t for concrete admixture and aggregate; \$25/t for horticulture and landscaping; and \$12/t for building block (Bolen 2003b; W.P. Bolen, personal communication).

Volcanic Cinders and Scoria

Scoria and volcanic cinder are cellular, frothy products of explosive volcanism erupted as tephra (blocks, bombs, lapilli, and gravel) or lava flows from mafic magmas. Scoria, which contains variable amounts of air holes (vesicles), is a lighter equivalent, usually of basalt. Much of the material is forcefully ejected from the vent, vesiculating in the air as the volcanic gases (mostly water) expand, and are entrapped by the rapid cooling of the relatively fluid lava. Scoria also develops where the gases are entrapped by rapid cooling at the surface of the flows; it may then be broken into blocks and irregular fragments by continued movement of the flows. There is a fairly wide range in vesicle size (particularly in the ejecta, most of which

have dense fused surfaces) and in the thickness of the cell walls, which results in a considerable variation in the density of the rocks.

The distinction between scoria and volcanic cinder is an arbitrary one of size; cinder is material less than about 2.5 cm (1 in.) in the largest dimension. Characteristically, mafic ejecta are fairly heavy and are not thrown long distances from the vent; they form cinder cones around the vent that are generally a few hundred to several thousand feet in diameter and several hundred feet in height. In contrast, mafic lava flows (basalt or basaltic andesite) tend to be fluid, several hundred feet to tens or even hundreds of miles in lateral extent, and a few feet to several tens of feet thick. The flows are seldom abundantly scoriaceous throughout; most of the vesicular zones are confined to the upper few feet of the flow and are highly variable in their development (Bush 1973).

Mafic vesicular volcanic rocks are widely distributed throughout the western United States, including Hawaii and Alaska, but are missing from the central and eastern states. Deposits of scoria and cinder are known in every state west of the 104th meridian, and production has been recorded from all states except Alaska. The largest producers are Arizona, Oregon, California, Hawaii, and New Mexico, but no one state is consistently largest; in 2002 New Mexico was the largest producer. The ranking in production does not always reflect the relative amounts of scoria and cinder available, in part because production is determined by competition and the size of the market within an economic range of the deposits and in part because, until recent years, the reporting of production included pumice and pumicite. In the states west of 104°, nearly all the metropolitan districts with a core city of at least 50,000 people and most cities of at least 25,000 are within about 100 miles of deposits of scoria or cinder, but not all can be served economically from them.

Cinder and scoria production is reported as part of crushed stone production by the U.S. Geological Survey (USGS), and production reports by the industry, though voluntary, are comprehensive. Because of the small size and intermittent operations of some of the enterprises, accurate production figures are sometimes lacking but, overall, are reliably representative.

Other Volcanic Rocks

Other natural lightweight aggregates in the western United States include variations on the volcanic rocks previously discussed. For instance, pumice is usually very silicic and could be considered a rhyolite if not containing abundant air voids. The air-void density often varies during emplacement, resulting in variable rock densities. Pumiceous rhyolites are currently used as a semi-lightweight aggregate in some western states and have been described by Bryan (1987). Specific gravities of pumice are generally <1.0 (indicating that it floats in water); specific gravities of pumiceous rhyolites that are used in concrete masonry units and structural concrete range from 1.8 to 2.3. Most western rhyolites are usually from 2.5 to 2.7. Pumice and the lower-density rhyolites are generally glassy.

Other volcanic rocks that have sometimes been evaluated in the western United States for potential lightweight applications are welded tuffs, rhyolites of volcanic domes, perlite rocks, and any recent volcanic rocks high in glass content.

Tuffaceous rocks are products usually of explosive volcanism, differing in chemical composition but characterized by lighter weight caused by the collapse of pumice vesicles as the ejecta lithify. Bryan (1987) described their geology, occurrence, and usage in the southwestern United States.

It should be emphasized that the lower-density volcanic rocks are concentrated in the western United States where Tertiary and recent volcanism is present. The eastern portion of the country

lacks young volcanism. Volcanic rocks in the East are generally much older and have been altered and metamorphosed to such a degree that no inherent lightweight characteristics such as glass or voids remain.

MANUFACTURED LIGHTWEIGHT AGGREGATE

Expanded Clay, Shale, and Slate

Many varieties of clays, shales, and slates of diverse origins expand somewhat on heating to about 1,100°C (2,000°F). Basically, all clays, shales, and slates are chemically and, to some extent, mineralogically similar; they differ mostly in their physical characteristics. These lightweight aggregates are used only for their physical properties, and it is their chemical similarity that makes all of them amenable to thermal expansion. See Table 67 in Bush (1973), which presents several representative chemical analyses for the argillaceous rocks that have been tested for use as lightweight aggregate. The range in composition is wide for each of the three materials, and all three ranges largely overlap. Unfortunately, the rocks that expand suitably, that expand inadequately, or that do not expand at all fall in these same ranges.

The basic requirement for expansion of an argillaceous rock is a source of gas within the raw material, but full suitability requires several other physical characteristics. Sufficient gas must form to cause a full bloat in the temperature range where the material is pyroplastic (melted enough to be viscous) so that the gas can be trapped; there must be enough vitrification at a high enough viscosity so that most of the gas can be held in small, evenly distributed pores; and the temperature range between softening and liquefaction must be large enough (about 38°C, or 100°F) that the bloating can be controlled in large-scale commercial production. Economical production is had at kiln or sinter temperatures between 1,000° and 1,200°C (1,830° and 2,200°F), although temperatures can be as low as 870°C (1,600°F) or as high as 1,300°C (2,400°F).

There is little agreement on the relative importance of the number of possible sources for the gas within the raw material. Conventional wisdom in the early days of the industry held that the argillaceous rocks had to have significant organic content, although the amount varied with the practitioner. Laboratory investigation of the evolved gases, however, showed that many materials with very little total carbon expanded better than those with appreciable amounts (Austin, Nunes, and Sullivan 1942; Sullivan, Austin, and Rogers 1942)—to perhaps 1.5%—and that CO₂, SO₂, and H₂O all played a part in the bloating. Riley's (1951) research indicated that thermal destruction of hematite, pyrite, and dolomite provided both CO₂ and SO₂ in amounts sufficient for bloating without recourse to organic carbon. Ehlers and Richardson (1958) emphasized the role of CO₂ derived by the heating of calcite, dolomite, and ankerite in argillaceous rocks, and by subsequent, more-effective entrapment in illite than in kaolinite (kaolinite fuses at a higher temperature than illite). They deemphasized the role of iron in gas liberation, considering its possible significance only where hematite exceeded 5% of the rock.

This history of investigations suggests (1) that opinion as to what causes bloating diverges considerably, (2) that no single factor is most important, and (3) that insufficient consideration has been given to the possible effects of the suggested reactions operating simultaneously, at least as far as the production of gas is concerned (Bush 1973).

Riley (1951) investigated the combinations of constituents that apparently acted as fluxes and affected pyroplastic conditions at the appropriate temperatures for gas formation and retention, and was able to define a range of compositions that included most of the bloatable materials and excluded most of the nonbloatable materi-

als (SiO₂, 52% to 80%; Al₂O₃, 11% to 25%; and combined fluxes, 10% to 25%). Additional investigations since 1951 have shown that this bloating range is less reliable than it first seemed, but it is a useful guideline. White (1960) showed that the range had to be extended in the direction of higher Al₂O₃ and lower flux contents, whereas Sweeney and Hamlin (1965) had to extend the range to a higher flux content. At the same time, materials previously considered to be nonbloatable were included in the bloating range. Conley et al. (1948), Klinefelter and Hamlin (1957), and Hamlin and Templin (1962) described laboratory methods for evaluating raw materials. The ultimate evaluation is how the material expands in a commercial operation; for this determination to be made, several tons of material may need to be run (Bush 1973).

Distinguishing between favorable and unfavorable rocks in the field is difficult because there are no really positive field criteria. Many different argillaceous rocks have been found to be suitable. Darker colored clays, shales, and slates (green, gray, black) are more suitable than light-colored (particularly red) ones; unweathered materials are more suitable than weathered ones; common or brick clay is more suitable both physically and economically than flint or ball clay. Thinly fissile shales and slates tend to expand unidimensionally, which is undesirable. Lateral variation along the sedimentary deposits is such that units unsuitable at one point may be eminently suitable a few hundred yards to a few miles away.

In addition to materials that can be made to expand, argillaceous rocks can be ground, mixed with combustible materials (such as ground coal), and sintered to produce lightweight aggregates. The mass becomes pyroplastic, or cohesive, and voids are left as the combustibles are burned out. Some bloating may occur, but it is incidental to the sintering. Because some clayey rocks that do not bloat can be used for lightweight aggregate, classifying any argillaceous rock as unfit is unwise unless it has been tested and found unsuitable. It must be noted, however, that as of early 2004, no lightweight aggregate was being produced by the sintering process (J.P. Ries, personal communication).

Air-Cooled, Granulated, and Expanded Slag

Of these three types of slag, past U.S. Bureau of Mines (USBM) and USGS production (Table 4) shows that air-cooled slag is the largest category by weight. The lightest air-cooled slag is as heavy as the heaviest lightweight aggregate; it is closer to a normal-weight, sand-and-gravel aggregate. Air-cooled slag is mostly used for road metal, road base and fill, portland cement concrete, and asphaltic concrete, and as railroad ballast (van Oss 2003).

The data for expanded slag cover foamed and pelletized slag, but the dominant data component in this category through 2001 was granulated blast furnace slag (GBFS), a material that has little use as lightweight aggregate. GBFS was put in the expanded slag category to protect proprietary data for both slag types. Granulated slag is formed by quench-cooling molten slag through a water stream to produce sand-sized grains of a calcium-silicate glass. This material, when very finely ground (even finer than portland cement), has moderate hydraulic cementitious properties but the cementitious properties become very strong when the material interacts with free hydrated lime, such as that which is released through the hydration of portland cement.

Expanded slag (foamed slag and pelletized slag) is, like GBFS, cooled quickly with water, and then the foamed slag is crushed and screened. The objective in making expanded slag using large amounts of steam is to create innumerable vesicles in the product. These vesicles make the slag lightweight and allow it to bond well with cement in lightweight concrete applications, the main use for expanded slag. Owing to the inclusion of more complete data in

2002, USGS was able to reveal data for GBFS separately for that year; but this required the withholding of expanded slag data for proprietary reasons. In a footnote, USGS noted that the tonnage of expanded slag sold in 2002 was <0.1 reporting unit (i.e., <100,000 t; van Oss 2003). It is likely that this magnitude of expanded slag sales has not changed significantly in a decade or more.

Data on blast furnace slag pertain to sales of processed material and not to production. Overall production of blast furnace slag is related entirely to the iron and steel market and hence to the output of crude or pig iron, yet the actual slag output is not routinely measured and so data on slag production are virtually unavailable.

ULTRA-LIGHTWEIGHT AGGREGATES (MANUFACTURED LOW DENSITY)

Expanded Perlite

Most perlite applications require the expanded form of the mineral. Run-of-mine perlite is crushed and ground before thermal treatment. Run-of-mine material is normally reduced in size by a jaw crusher. Depending on the end use, it may then be further reduced by cone crushers and then air classified (McMichael 1989). Domestic crude perlite is produced primarily in the western United States. In 2002, New Mexico and Oregon accounted for about 85% of domestic production. The remaining production comes from Arizona, California, Nevada, Idaho, and Utah (Bolen 2003a). The largest foreign producer of perlite is the Greek firm S&B Industrial Minerals SA, with its main deposit on the island of Milos and other deposits on Kos, on Sardinia in Italy, and near Biga in Turkey (Burke 2004).

Expanded Vermiculite

Flakes of raw vermiculite concentrate are mica-like in appearance and contain water molecules within their internal structure. When the flakes are heated rapidly at 900°C (1,650°F) or higher, the water flashes into steam and the flakes expand into accordion-like particles. The color, which can range from black and various shades of brown to yellow for the raw flakes, changes to gold or bronze on expansion. This expansion process is called exfoliation, and the resulting lightweight material is chemically inert, fire resistant, and odorless. Vermiculite provides good thermal insulation in lightweight plaster and concrete. It can absorb such liquids as fertilizers, herbicides, and insecticides, which can then be transported as free-flowing solids (Harben and Kuzvart 1996). In 2002, the two U.S. producers of vermiculite concentrate were Virginia Vermiculite Ltd., with operations near Woodruff, South Carolina, and in Louisa County, Virginia; and W.R. Grace & Co., with its operation at Enoree, South Carolina (Potter 2003).

A USGS study analyzed the mineralogy of vermiculite-rich samples collected from 62 U.S. vermiculite mines and deposits (Van Gosen et al. 2002). The purpose of the study was to determine if amphibole asbestos minerals similar to those found in the Libby, Montana, vermiculite deposit were present in other U.S. vermiculite deposits. The results of this survey suggested that fibrous amphiboles, in more than trace amounts, may not be common in the ore zones of some types of vermiculite deposits. But initial results also suggested that vermiculite deposits that can contain fibrous amphiboles occur in geologic settings similar to the Libby vermiculite deposits—within zoned, alkalic-calcic, quartz-poor plutons, especially plutons with characteristics of carbonatite intrusions. Additionally, vermiculite deposits found where masses of ultramafic rocks are cut by granite or pegmatite can contain amphibole fibers. The results of this mineralogical survey were preliminary, and additional sampling is planned. These relations may help guide priorities for sampling, reclamation, permitting, and monitoring of

active and inactive vermiculite mines. Additional comments on the occurrence of vermiculite can be found in the chapter on vermiculite in this volume.

Some discrepancies exist in the data for vermiculite given in Tables 4 and 5 for 1996 through 2002. This is due in part to differences in the data reported for production and for values in the *Minerals Engineering* information compared to data given by the USBM and USGS. The data from the latter bureaus are constrained by the prohibition against publishing proprietary company data when three or fewer companies are the source of the data. This is the most common reason for the estimated figures in the tables.

OTHER MATERIALS USED AS LIGHTWEIGHT AGGREGATE

Diatomite has reportedly been used as lightweight aggregate, but this use has not been verified; therefore, diatomite is not discussed here. Organic products such as rice hulls, straw, and peat have also reportedly been used in the past as a lightweight aggregate, but they are considered insignificant and are also not discussed.

Coal cinders contribute to the production of ash, more in the southwestern United States than in other parts of the country. Municipal waste combustion produces bottom ash (all solid materials that pass through the furnace unburned, such as tramp metal, plastics, glass, rocks, and dirt). Most coal-consuming end waste processes produce fly ash rather than cinders, so fly ash production continues to increase with both the increased use of pulverized coal in electric power generation and with waste incineration. Approximately 600 kt of fly ash are produced annually, but utilization is only about 13% (Kiser and Zannes 2002). The production of lightweight aggregate from fly ash has potential as a significant market, but improvement in the technology is needed to spur use as a lightweight-aggregate raw material.

Incinerating municipal waste leaves a residue that is a minor source of lightweight aggregate. In 2004 there were 89 waste-to-energy plants in 29 states that handled about 13% (29 Mt) of the approximately 200 Mt of solid waste generated in the United States. In 2003, Kiser and Zannes (2004) estimated that about 600,000 t of ash per year was used as aggregate in road material and as landfill cover.

Most states have now adopted legislated recycling goals. Under the Resource Conservation and Recovery Act (RCRA), passed in 1976 and reauthorized in 1993, the U.S. Environmental Protection Agency (EPA) issued regulations that govern the disposal of fly ash and bottom ash in landfills. Additional pressures have made it necessary to develop alternate means of disposal and alternate uses, and in the ensuing years, many new plants have come onstream to process municipal solid waste and sewage into a lightweight aggregate. The process combines pulverized municipal solid waste (recyclable and oversized material removed) with a mixture of milled clay and liquid nonhazardous waste (sewage sludge) to form a pellet. The pellet is processed through a three-stage kiln. First, the pellet is pyrolyzed (chemically altered by heat), which allows combustible gases to escape. These gases bloat the pellet into a lightweight aggregate but also provide some of the required fuel for the kiln. In the second stage, oxidation removes most of the pellet's carbon, enhancing the lightweight property of the aggregate and supplying some of the energy requirements of the process. In the third stage, the pellet is vitrified.

This process has been in development for about 12 years. It is projected to be self-sustaining with respect to its energy requirements. Income is expected from solid waste disposal fees, use of nonhazardous liquids, and the sale of recovered recyclables. The aggregate is expected to be marketed for approximately \$33/t.

Table 7. Perlite uses in the United States, 1990 and 2002, %

Uses*	1990	2002

* May exceed 100% because of rounding.

† Included with other uses in 1990.

Questions abound, however, about whether this process will pass present air emissions standards and if the lightweight product will be accepted in the marketplace. In 1988 a pilot plant was operated as a test facility near Brisbane, Australia, and many technical process problems were encountered. This process has also been tested in Germany (Bigner 1992; Gershman and Miller 1992).

PRODUCTION AND CONSUMPTION

Table 4 summarizes the annual output of lightweight aggregates in the United States for 1990 through 2002 by quantity, and Table 5 summarizes the stated values of lightweight aggregate production for the same period. Because complete data for 2003 are not available, they are not included in Tables 4 and 5. Where any data were available, however, they are discussed in the text. Table 6 compares the average unit value of lightweight aggregate materials at production plants in 1990 and 2002. From 1990 to 2002, significant price increases for expanded perlite (Table 7) and exfoliated vermiculite gave them a large share of the market in terms of value (approximately 32% in 2002) despite contributing only about 5% of the tonnage. Expanded shale, clay, and slate are widely used and in 2002 they accounted for about 39% of the quantity and 27% of the value of the market.

Natural lightweight aggregates are mostly bulky and of low unit value and normally serve local and regional markets. Some structural lightweight aggregates, however, are economically shipped long distances because the density of these aggregates are one half to one third the density of locally available normal-weight aggregates such as crushed stone, sand, and gravel, and any comparisons should be made on a volume basis. For example, lightweight aggregate may be four times as expensive per ton as local normal-weight aggregate but may yield two to three times its volume. One ton of lightweight aggregate will normally make two to three times as much concrete end product as 1 t of normal-weight aggregate (Gershman and Miller 1992).

Products such as pumice or expanded slag may be used in substantial quantities in some localities and may not even be available (at competitive prices) in others. Perlite and vermiculite deposits are limited in location but serve national markets because of their relatively high market value and because their ores are shipped prior to pyroprocessing and physical expansion. Most of these pyroprocessing and expansion plants reflect specialty uses in regional and national markets. The more specialized uses command higher market prices that lead to extensive geographic distribution and use (Mason 1994).

Expanded clays, shales, and slates make up about 50% by weight of the lightweight aggregates used annually in the United States, with the remainder divided among volcanic cinders and scoria, expanded blast-furnace pelletized slag (excluding air-cooled and nonpelletized granulated types), fly ash, vermiculite, and perlite. Vermiculite and perlite are the most used ultra-lightweight materials, but less than 25% is used as construction aggregate. They are used in about equal amounts. Pumice constitutes the remaining third of that market (Bush 2001).

About 8.1 Mt of rock were used in 2002 for structural lightweight aggregates, and perhaps as much as 0.55 Mt were used for ultra-lightweight aggregates for nonload-bearing concretes, blocks, plaster insulation board, fillers, filters, agricultural aids, and loose fill insulation.

Because the lightweight aggregate industry is largely dependent on the overall construction industry, production follows the level of activity in home, building, highway, and bridge deck construction. Energy costs are a dominant factor wherever raw materials need to be heated for expansion.

Details on the production and sales value of pumice and pumice are given in the section on natural lightweight aggregates in this chapter.

Consumption of expanded clay, shale, and slate increased from about 1.09 Mt in the early 1970s to 4.0 Mt in 2002 and has hovered in the 3.9 to 4.0 Mt range since 1995. Sales generally reflect the state of the construction industry, and the use of lightweight aggregates in concrete block, structural concrete, and highway surfacing. In 2002 the average value of crude ore was \$13.69/t, and the average prices of expanded clays, shales, and slates ranged from \$30/t to \$50/t at the plant, depending on gradation and aggregate type (J.P. Ries, personal communication). Tables 5 and 6 show typical values for lightweight aggregate raw materials (ores) and the expanded products at the production plant.

Prices more than doubled in 10 years from \$11/t to \$20/t in the early 1980s (McCarl 1983), up to \$33/t to \$57/t (depending on gradation and aggregate type) in 1990 (J. Konczak, personal communication). As shown in Tables 5 and 6, cost trends for raw materials between 1990 and 2002 have been variable. Exfoliated vermiculite and expanded slag showed significant price increases (170% and 270%, respectively), vermiculite concentrate and perlite (both crude and expanded) remained virtually static, and raw clay and shale have decreased 44%.

The sales tonnages in the 1980s (1.1 to 1.7 Mtpy) reported by Mason (1994) for expanded slag reflected USBM data for expanded slag combined with granulated slag and were dominantly of the latter, which, when pelletized, was the only slag-based material produced in 2002 used as a lightweight aggregate. Sales of processed slag are almost entirely from stockpiles, some of which may be very old, and are related to construction-sector demand. This demand has also influenced the type of cooling applied to newly formed slags, to the degree that a blast furnace is equipped for cooling options. For both standard and lightweight aggregate markets, slags must compete with natural aggregates (including crushed stone) in a market that is highly sensitive to transportation costs. High transportation costs and, especially, the ease of formation of air-cooled slags (these are cooled under ambient temperature conditions) have long favored the production of air-cooled slag.

Ground GBFS (worth about \$60/t) finds a ready market as an admixture in blended and masonry cements and, especially, as a partial substitute for portland cement in concrete:

"...the growing market and high unit price have led to the addition of granulators at some existing U.S. blast furnaces. At [three]...facilities in Indiana, pelletizers have

also been added, ...which implies that U.S. output and sales of pelletized slag will likely increase from current very low levels beginning in 2003 or 2004" (van Oss 2003).

Unground GBFS is worth about \$30/t, and \$60/t ground; pelletized GBFS is worth roughly \$20/t, so the processing economics in handling the molten and then cooled material are similar.

A major factor in the expanded plus granulated combination is that for the past few years, sales of GBFS ground in the United States from imported unground blast furnace slag were not included. Beginning mid-2003, USGS tried to find all the locations where this material was being handled (including those grinding imported materials). More complete data collection allowed USGS to directly report the granulated slag sales for 2002 (see Table 4), but the 2002 data for expanded slag continued to be withheld for proprietary reasons.

The unit value (about \$13/t in 1990) in Mason (1994; Table 6) for expanded slag increased to about \$35/t in 2002 (T. Wagaman, personal communication); most of the price shifts reported in the intervening years for this (combined) slag category reflect shifts in the data for the granulated slag component.

According to an industry expert, "In terms of the future—granulated sales should at least hold steady and likely will increase. Imports of this material will increase" (H.G. van Oss, personal communication). Expanded (pelletized) slag sales are likely to increase, with the introduction of two pelletizers by Inland Steel Corporation in 2003 (in East Chicago, Indiana).

INDUSTRY STRUCTURE MINING AND PRODUCTION TECHNIQUES

Natural Lightweight

Overall, the industry is characterized by many producers of raw material that do not manufacture the finished product. Among the natural lightweight aggregates, many producers of raw pumice also produce the final product—concrete masonry units, for example—or grind a product that is shipped directly to distributors; others ship unprocessed material to independent processors. Volcanic cinders and scoria are mostly used by the raw material producer to make concrete masonry units close to the quarry site, but some is shipped to independent producers. Rhyolite tuff is used as dimension stone and as aggregate; therefore it may be shipped to independent applicators far from the quarry site.

Mining and processing of pumice and volcanic cinder is simple and straightforward. They are extracted, crushed, and screened, similar in most respects to an ordinary sand-and-gravel deposit. In most cases, the younger materials are fairly unconsolidated and do not require ripping. Older pumice and cinder may be consolidated and do require ripping. Most processed pumice does not require washing for end use; specialty uses may require some washing. Pumiceous rhyolite or tuffaceous rocks are mined in a common quarry operation and thus requires blasting.

Many cinder deposits in the West are also used as a substitute for, or in competition with, ordinary-weight aggregates such as sand and gravel or crushed stone. Often cinder is the cheapest and most easily available material for road surfaces in some of the volcanic terranes in the western United States.

MANUFACTURED LIGHTWEIGHTS

Expanded Clay, Shale, and Slate

The manufactured lightweight aggregates are expanded clay, shale, and, to a lesser amount, slate. In the eastern and western parts of the United States, expansion is commonly done near the quarry site by the raw material producer; in the central part of the country, particu-

larly where transportation by water is available, raw material may be mined hundreds of miles from the expander and sold to independent producers located near the eventual market.

Shale, clay, and slate are normally mined by open-pit and quarry methods, and then dried in large sheds or open stockpiles to control water content in the raw feed before high-temperature pyroprocessing in either rotary kilns or sintering machines. The resulting clinker may then be screened or crushed before screening to yield proper gradation mixes for final use as an aggregate in concrete masonry units, structural concrete, or other applications. The specific gravity of the expanded shale, clay, and slate can be controlled to some degree by the type of kiln or sintering grate used to process the raw material (Mason 1994).

Most producers of expanded shale, clay, and slate find long-run economic survival precarious if they do not engage in substantial raw material testing, geologic and mining studies, and marketing research investigations before selecting the location of a new plant (Conley et al. 1948; Shildeler 1961).

Production costs for expanded shale, clay, and slate have increased in general along with the cost of energy, raw materials, and supplies. In recent years the additional cost associated with the installation of air pollution control equipment (baghouses) has had an effect on operational costs. The cost of labor is considerably higher today in proportion to other cost centers. More direct cost increases were felt as more power was required per unit of production than in the past. Conservation efforts continue to lower the costs of energy-related items, such as refractories and electric power. Most plants continue to use coal or petroleum products as a primary source of fuel (Mason 1994).

Several producers are now using alternate fuels to fire kilns. Some of the alternate fuels are better known as *waste-derived fuels* and solvents from various industrial processes. Waste-derived fuels can be excellent, low-cost fuels, as long as air-emissions parameters can be met. In some cases the producer using these fuels receives an income stream from the generator of the fuel. This has caused some market distortions but has kept production costs stable while providing a reasonable method of disposing large quantities of waste that does not threaten human health (Singletary 1991; Kelly 1992; Kiser and Zannes 2002).

Expanded clay and shale are the most used and the most valued lightweight aggregate materials for structural applications. As with most aggregates, normal or lightweight, mining is by open-pit methods, using drilling and blasting where necessary. Mason (1994) pointed out the need to dry quarried material before processing with either of the two expansion methods: rotary kiln or traveling grate sintering machine. According to the ESCSI (J.P. Reis, personal communication), there has been no sintered production since 1996. The raw feed enters the kiln at the high end, if the kiln is inclined, to take advantage of gravity flow down through the kiln. Usually there is a preheating section, using waste heat from the burning (bloating) zone, and the feed then traverses the burning zone rapidly to avoid agglomeration and sticking to the lining of the kiln. It then goes through a cooling section and is discharged, further cooled, and stockpiled. Crushing and size grading precede the kiln, and grading follows the expansion. Usually the bloated material is graded into coarse ($3/4$ to $3/8$ in.), intermediate ($3/8$ to $3/16$ in.), and fine ($<3/16$ in.) sizes and is then mixed to satisfy the specifications for end uses. Additional detail can be found in the chapters on structural clay products and common clays and shale in this volume.

Slag

By-product lightweight aggregates are expanded (foamed) and pelletized GBFS. Slag producers are not usually the distributors and

are rarely the end-market distributors; they are iron and steel producers who can take advantage of a market for their unavoidable by-product. Fly ash and bottom ash result mostly from coal combustion and significantly from incineration of other materials—to a large extent, municipal waste. Their use is primarily local, except for the amount used to serve the cement industry, which finds the ash's pozzolanic properties attractive as an admixture to portland cement.

Expanded Perlite and Vermiculite

A very important segment of the manufactured lightweight aggregate market is the ultra-lightweights: expanded perlite and expanded vermiculite. Comparatively little use is made of the raw materials in the unexpanded form; both have to be processed at high temperatures to achieve expansion.

Perlite is not a commodity dominated by a single producer. There are too many well-distributed deposits of economic size to capture the market. Of the fewer than 20 producers in 2003, only a few had more than one mine and most of them had their own expansion facilities, although there was some shipment of crude ore to independent expanders.

The history of the vermiculite industry is quite different. Early in the 1920s, a very large vermiculite deposit was discovered near Libby, Montana, and it became the dominant source in the United States for more than 50 years. As a result, a vertically organized business structure developed, with many company-owned or franchised expanders throughout the country. Additional sources came into the market from South Carolina in the late 1940s and thereafter, serving mainly the eastern part of the country, but still as part of the single business structure. The U.S. market attracted imports of crude vermiculite ore after World War II (a available data was first reported in 1950) and sales were made to independent expanders, mostly in the Gulf Coast and eastern seaboard metropolitan areas.

Active mining and milling of vermiculite ore at Libby ceased in 1990, and all shipments of stockpiled ore concentrate ended in 1994. Health problems were factors in that decision, and subsequent publicity led to a marked decrease nationwide in the sales of exfoliated vermiculite. From 1993, vermiculite sold and used decreased from about 190 t to an estimated 175 t in 2000, and then dropped precipitously to 115 t in 2002. The 1994 volume of *Industrial Minerals and Rocks* listed 41 expansion plants in the United States, with 24 producers. The nationwide concern about asbestos led to a survey by the EPA to identify the sites of all exfoliation plants, both past and present (D.H. Thornton, personal communication). Despite the decrease in volume, by 2003 there were, or had been, at least 245 exfoliation plants, operated by about 139 companies. One company operated, franchised, or leased 52 plants. There was one exfoliator in Hawaii and one in Puerto Rico; none is recorded in Alaska (K.C. Land, personal communication).

Since 1990, there has been a very marked decrease in the number of company-owned and franchised expanders, coupled with the availability of crude ore from additional sources in Virginia and South Carolina. Additional comments can be found in the chapter on vermiculite in this volume. New imports from mainland China entered the market in the 1990s and are serving independent expanders, largely along the West Coast but also reaching into the central United States from Gulf Coast ports.

Expanded perlite is subject to two factors of perhaps equal importance. The ore must be carefully and selectively graded, with end usage clearly in mind before "popping," and the ore has to be passed through the hot zone in the furnace under closely controlled time and temperature conditions. Crushing and sizing are done by jaw crushers (primary stage), followed by drying and crushing by

cone crushers (secondary stage), additional drying, and additional crushing (third stage), followed by classification using vibratory screens and forced air. The preexpansion of the raw ore to about 1% surface moisture can alleviate a number of problems in the expansion process. Other ways to crush the ore, depending on its structure, include impact, rod, and hammer mills; roller crushers; and gyro discs. After storage by size, a mix appropriate to the expander's usage is blended and then shipped to the popping plant.

The popper may be one of two major, contrasting types—vertical (or semi-inclined) or horizontal (stationary or rotary, cocurrent or countercurrent)—or a third type, the TORBED (toroidal fluidized bed) process (Clark 1984), which has not found wide acceptance and is mentioned here only to be inclusive. The most commonly used expander is the vertical furnace, particularly for coarser-grade perlite used in horticulture; for finer grades, either can be used efficiently. In the vertical furnace, raw ore is dropped from the top or added through side ports, usually with some preheating. The amount of preheating and the residence time in the hot zone are carefully controlled so that the ore is at its most optimum condition for expansion. In the hot zone, the residence time is usually limited to a few seconds to prevent overexpansion, which can lead to bursting the perlite bubbles. Expulsion from the furnace may be by forced air, by fan suction from or near the top of the furnace, or by simply riding the current of rising hot gases. In the rotating horizontal furnace, the ore enters at the hot zone and spiral baffles in the rotating cylinder propel it the length of the furnace. This allows for a slower cooling rate of the expanded ore (an often desired element in the processing). The horizontal furnace may actually be inclined to allow gravity to help transport the perlite, and the flow can be either cocurrent or countercurrent, taking advantage of the radiant heat from the cooling zone to preheat the incoming air (in a jacket around the furnace) on its way to the combustion zone.

The chapter on perlite in this volume covers expansion and product processing, testing, and specifications in considerable detail, and the reader is referred to it for further information. In 1994, the Perlite Institute published a handbook on test methods and related standards for perlite, and it is an invaluable reference. The institute's Web site (www.perlite.org) lists many publications on the specific details of horticultural, structural, and insulatory applications.

Expanded vermiculite is made at about 900°C (approximately 1,650°F), although the appropriate temperature varies with the ore from deposit to deposit, depending on the degree of alteration from the parent biotite or phlogopite. Almost all expansion is done in vertical furnaces, although for the finer grades a horizontal rotary furnace can operate efficiently.

Milling and beneficiation are almost universally done now by wet methods (flotation). The need to effectively offset the association of asbestiform (tremolite) minerals with vermiculite at the Raily Creek deposit on Vermiculite Mountain near Libby, Montana, and the dust-producing dry beneficiation methods used there until 1970, led to a complete replacement by the wet process. Wet beneficiation requires a drying stage at an additional screening station before the concentrate can be crushed and sized. The Vermiculite chapter in this volume compares beneficiation methods and flowsheets, and also discusses testing, specifications, and particle-size ranges of the preexpansion concentrate required by exfoliation plant operations destined for different products.

There has been little change in vermiculite processing technology since the publication of the 6th edition of *Industrial Minerals and Rocks* in 1994; the Vermiculite chapter in this volume covers the technology so thoroughly that the information is not repeated here.

FINISHED PRODUCTS AND SPECIFICATIONS

Concrete Masonry Units

Concrete masonry units (block) are the predominant concrete product using lightweight aggregates, both natural and manufactured. In the West, most block plants use natural lightweights to at least some degree, if the block plant is within a favorable shipping distance from the source. In the eastern United States, manufactured lightweights predominate. Usually the aggregate is shipped to the plant closest to the market. Often, shipping is by rail if the plant is within a few hundred miles.

The standard block is what is referred to as an 8-8-16, reflecting the dimension in inches, and it contains two hollow cores. The blocks are manufactured in machines that accept a mix of cement, aggregate, and water that is vibrated for consolidation into molds. The resulting texture of a block is more porous than poured concrete. Other size blocks are also manufactured with various dimensions for specialty applications or for architectural needs. For instance, *split-face block* is a larger block that is mechanically broken to expose the inside of the block and to create a rougher texture. To create a certain architectural look, the blocks are often colored, and certain aggregates are chosen also for their color.

Concrete block strengths primarily depend on the cement content and the physical properties of the aggregate used. Often a lightweight coarse aggregate is a major ingredient, with the finer size being ordinary-weight sand; this ensures a lighter block but also one that has strength suitable for structural applications. Block strengths can exceed 4,000 psi (27,600 kPa). Block is used in various applications ranging from fences to high-rise construction.

Blocks are laid in horizontal courses and mortared together to create structures. Probably the main reason for using a lightweight aggregate in block is productivity. A mason can lay more 25-lb block in a day than 35-lb block. For most applications, the hollow cores are subsequently grouted solid with a sanded concrete mix. In addition, steel rebar is generally placed in the cores for added strength. Local building codes and the design of the individual structure govern the strength and other characteristics of the block. The standard specification for concrete masonry units is ASTM C331-04, *Standard Specification for Lightweight Aggregates for Concrete Masonry Units*. This specification outlines in detail the required weights for lightweight aggregates and also gives gradation, shrinkage, and other criteria on limits for deleterious materials and the durability of the finished product. It should be understood, though, that even if some aggregates do not meet these weight requirements, they can be considered a semilightweight and used in block. Local building codes and individual job specifications govern the physical properties of the end product. Often, it is more economical to use a close source of semilightweight aggregate, such as volcanic rocks in the western United States, than it is to use a manufactured lightweight aggregate that is located several hundreds of miles from the project.

Lightweight Structural Concrete

Lightweight structural concrete is usually batched like any other ready-mix concrete in central plants or on-site plants that deposit the wet mix into a ready-mix truck, which transports it to the job site. Ready-mix concrete is more fluid than mix for concrete masonry units but essentially consists of cement, aggregate, and water. A mix design takes into account criteria for strength and weight of the finished product. Often the lightweight material is only a portion of the coarse fraction of the aggregate used in the mix, with ordinary-weight sand making up the fine fraction. In certain western U.S. locations, where semilightweight natural aggregates are available, the entire mix is lighter-weight aggregate.

Lightweight aggregate primarily reduces weight in structures. Reducing weight reduces construction costs, because structural members can be smaller when holding less weight. Lightweight is especially called for in suspended concrete floor slabs aboveground and in structural columns for high-rise buildings.

The generally accepted specification governing lightweight aggregate is ASTM C330-04, *Standard Specification for Lightweight Aggregates for Structural Concrete*. This specification outlines in detail the required weights for lightweight aggregates and also gives gradation, shrinkage, and other criteria on limits for deleterious materials and the durability of the finished product. Other state and federal specifications may be applicable depending on the concrete usage and the structure's owner.

The Aggregates chapter in this volume contains a more detailed discussion of aggregate usage in portland cement concrete.

Insulating and Fire-Resistant Materials

Lightweight aggregates by their nature also enhance the insulating and fire resistance of a structure when incorporated in concrete products. The air voids in a typical lightweight aggregate act as an insulator. Typical lightweight aggregates increase the R value (the resistance value of structural components such as floors, ceilings, and walls; the higher the value, the more insulation value). ASTM C330-04 applies to two general types: (1) those prepared by expanding, pelletizing, or sintering (blast furnace slag, clay, shale, or slate, fly ash, and diatomite); and (2) those prepared by processing natural materials (pumice, scoria, or tuff). ASTM C331-04 covers these types and adds aggregates consisting of end products of coal or coke combustion. ASTM C332-99 outlines the necessary insulating and grading requirements for lightweight aggregates for the ultra-lightweights such as expanded perlite and vermiculite; the two types are described in ASTM C330-04. Generally speaking, the lighter the weight, the better the insulating and fire-resistant properties of the material.

Other Products

New developments in lightweight aggregates in construction have been robust, and this trend will continue as supplies of "conventional" aggregate tighten. A relatively recent innovation is the use of lightweight fill in certain applications where heavier materials would contribute to settlement. Such a use is in the San Francisco area, where the notorious "Bay Muds" are bottomless. Thousands of tons of pumice from northern California are used as fill to support highway structures crossing these muds. Other construction-related innovations include using expanded shales on pavement surfaces for skid resistance.

Numerous applications for lightweight aggregate materials exist outside the construction industry, especially for expanded perlite and vermiculite. These are discussed in their respective chapters in this volume. One often-cited and unusual agricultural use in the 1980s was for bedding on a crocodile farm on the south coast of Natal, South Africa. Female crocodiles apparently became upset because there was no vermiculite—which was being used as a substitute for river sand to nest crocodile eggs—because a shipment of the material was delayed (Griffiths 1989).

ECONOMIC FACTORS

Price Trends

Prices for manufactured lightweight aggregates have risen dramatically in the past 10 years because of general inflation and higher energy costs. Fuel and transportation costs continue to rise. Other energy costs such as electricity for electric power are continuing to increase more rapidly than inflation. Cost of refractories is significant because prices reflect higher energy costs in manufacture.

Similar increases have been influencing the costs of expanded perlite and exfoliated vermiculite. Prices of lightweight aggregates will continue to reflect the rising cost of energy, and prices are likely to parallel energy costs.

Transportation

All forms of surface transport are used in moving lightweight aggregates. Truck transport is especially important in the delivery of expanded aggregates either in bulk or in containers. Economics of lightweight aggregate haulage are very similar to transportation of crushed stone and other aggregates. Because of the higher value of lightweight, however, some additional haulage can be tolerated with proportionately less delivered price impact. Transportation costs are likely to amount to 15% to 35% of the delivered price for most structural lightweight. The effect of transportation costs on delivered prices of vermiculite and perlite is naturally less because of the higher unit value.

A good rule of thumb is that distance of movement of aggregate materials is likely to be directly proportional to unit price and inversely proportional to unit weight and bulk. Perlite and vermiculite ore is air transported by rail from mines to delivery points throughout the United States and by ocean freighter throughout the world. Some vermiculite ores come to the United States by ship from South Africa, and rail haulage from the western United States to the East Coast is common. Exfoliated or expanded products, however, are not likely to be distributed outside local and regional markets because of their great bulk.

Rail transportation of other lightweight aggregates is largely regional; it is normally limited by the proximity of competing producers. Trucking may be local or regional depending on the availability of rail transport and relative costs. Trucks are normally most economical for hauls of 80 km or less; railroads are best suited for hauls in the 160 to 480 km range. The transportation method used is dictated by access to other competitive modes and by haulage costs. The object is to keep delivered price down to maximize returns to the producer.

Marketing

Most producers of natural and manufactured lightweight aggregates maintain their own sales staff and technical service representatives; some producers market products through brokers. Products are sold on the basis of specifications and cost-in-place of the final material. Often the ability to reduce dead loads (the weight of concrete in structures) by using lighter aggregates (in the concrete) will reduce the cost of structural steel. Insulation properties of ultra-lightweight aggregates in concrete and masonry units may enable the construction of thinner walls or reduce the need for other insulation. These factors often permit savings in building construction despite higher unit prices for lightweight aggregate. Product yield commonly can be improved by using manufactured lightweight. Surface textures and uniformity are commonly superior to naturally occurring or by-product aggregates.

By-product materials are normally handled by wholesale and retail dealers. The actual producers often handle slag sales, but cinders, fly ash, coke breeze, and other by-products are usually sold through brokers.

Producers of vermiculite and perlite ores generally license or franchise brokers for the exfoliated or expanded product. The raw material supplier gives trademarks, promotional materials, specifications, and other sales aids to the licensed or franchised dealer. The dealer pyroprocesses the ore and packages the product in bags or ships in bulk. The dealer acts as wholesaler in the distribution to large users and retail building material outlets.

Marketing research studies are usually important in the location of a new lightweight aggregate plant. The actual and potential use of lightweight aggregate materials in the intended market must be measured or estimated from planned and prospective construction trends. The proximity of competitors and transportation costs in the market area must be carefully studied to determine the economic feasibility of a new production plant.

Lightweight aggregate producers that do not maintain a marketing research department are advised not to initiate a new plant location without some market analysis. The choice of a consultant or specialized marketing research firm should be based on both the cost of the service and past experience in similar or related evaluations.

GOVERNMENT, ENVIRONMENTAL, AND HEALTH CONSIDERATIONS

Taxes, depreciation, and depletion allowances for lightweight aggregate producers are similar to those for producers of other construction materials. Zoning and land-use regulations are restrictive in urban and other heavily populated areas, and they are closely related to the situations encountered by producers of crushed stone or sand and gravel. The more limited occurrence of lightweight aggregate raw material deposits and the smaller number of producers, however, generally lead to the location of plants at greater distances from the more heavily populated market centers. Thus, lightweight aggregate producers tend to have fewer problems with zoning and land-use regulation. Where plants are simply pyroprocessing raw materials mined at distant locations or handling by-products, they are in the same category as heavy industry and are located in industrial areas.

As of mid-2005, there have been no significant reductions in government regulations on air and water pollution. Environmental standards continue to present challenges to the industry. If environmental standards are relaxed, there will be some cost savings, but not necessarily any significant reduction in production costs. The same observation can be made for safety and health regulations. Once implemented, the additional costs must be included in operating costs. Any relaxation in government regulations could, of course, hold down future cost increases.

Severe health problems associated with mining and milling of the vermiculite ore body at the Rainy Creek deposit near Libby, Montana, resulted in closure of the mine in 1990. The vermiculite deposit contains the asbestiform minerals tremolite, winchite, and richterite in the gangue; they were removed by dry concentration methods until 1970, when the process was replaced by wet concentration. Stockpiled ore shipments ended in 1994. Withdrawal of Libby vermiculite from the market and the attendant publicity about health problems had a major depressing effect on the vermiculite industry (see Tables 4 and 5). Sole domestic raw ore production has been from one deposit in Virginia and a number of deposits in South Carolina. Imports of ore increased from South Africa (ore from Palabora is reported to be free of asbestiform minerals), which, in turn stimulated imports from China and Brazil; China imported mostly to the West Coast, other imports were mostly to ports in the Gulf of Mexico, along the Mississippi River, and to the southeastern U.S. coast.

FUTURE OUTLOOK

Increase in the output of structural lightweight (suggested by the production figures in Table 4) is related to construction activity, which has been vigorous for several years. Even though gains in market share against conventional crushed stone and gravel for comparable applications have not been as robust as expected, structural lightweight should be expected to sharply gain in popularity

as aggregate supplies tighten. Lightweight should have a promising future because construction professionals will inevitably look more seriously at material replacements as mining for conventional aggregates gets more difficult and expensive. The costs of producing structural lightweight aggregates are related to the costs of energy and raw materials. Transportation costs of the finished aggregate have always had an effect on the price of the various lightweight materials available in the marketplace.

In the future, total consumption of lightweight aggregates will be more closely tied to the construction industry as lightweights are used as replacements in conventional applications, rather than being a function of specialty markets.

Mason (1994) indicated that demand for natural lightweights (specifically, pumice and volcanic cinders) appeared to be increasing over demand for manufactured lightweights, primarily because of their price benefits. Since then, however, industry consensus has tended to ward the opposite—more recently, field practitioners of concrete technology have preferred manufactured lightweights because the water content is much easier to control. Although demand for insulating materials has increased with rising energy costs, a persistent trend since the 1990s, overall perlite and vermiculite consumption have continued to sharply decrease (Bolen 2003a; Potter 2003). The decrease can be attributed, at least in part, to new developments in insulation that are beginning to replace older materials such as perlite. This will have an impact on markets for lightweight aggregates.

Tightening supplies of conventional aggregate, new innovations in manufactured lightweights, and further increases in energy prices should stimulate growth in demand for lightweight aggregates. Growth in demand for commodities used in manufactured lightweights, such as expanded clay, could exceed 4% per year, based on current trends (see Table 4). Demand for commodities used in natural lightweights, such as perlite, should continue to decline as manufactured lightweights gain popularity.

Because the final products of the lightweight aggregate industry have traditionally been energy-efficient buildings, the future of the sector will doubtless be closely linked to energy conservation trends. Insulation qualities of lightweight aggregates will continue to generate markets for these materials, but structural applications may gain prominence as new developments in insulation detract from the importance of lightweight aggregates in energy-efficient buildings.

ACKNOWLEDGMENTS

Many people from industry, state and federal agencies, and academia freely contributed information for this chapter. In many instances, their information is from the references listed or is credited in the body of the text. Still others shared information, insight, and data, but sheer numbers do not allow them to be separately credited here; to all of them, the authors extend sincere gratitude.

Asbestos

Robert L. Virta

INTRODUCTION

Asbestos is the generic name given to six fibrous minerals that have been widely used in commercial products. An industry term rather than a mineralogical term, it is applied to mineral particles that possess high tensile strengths, large length-to-width ratios, flexibility, and resistance to chemical and thermal degradation. Asbestos also exhibits high electric resistance, and many forms can easily be woven in textiles. Asbestos particles generally comprise bundles of fibrils, which are the smallest crystalline units of asbestos. These fibrils typically are less than 50 to 70 nm in width and can be several hundred nanometers in length. Fibrils compose the fibers seen under the light microscope and in hand specimens of asbestos. In regulatory discussions, the terms *fiber* and *fibril* are often used interchangeably.

The six types of asbestos that have been recognized in commercial use are: actinolite asbestos, amosite, anthophyllite asbestos, chrysotile, crocidolite, and tremolite asbestos (Table 1). Chrysotile is the asbestiform variety of serpentine; the other five are amphiboles. Crocidolite and amosite are the asbestiform analogues of riebeckite and grunerite, respectively (Campbell et al. 1977; Ross, Kuntze, and Clifton 1984; Skinner, Ross, and Frondel 1988). Magnesioriebeckite from Bolivia has been used commercially although it was marketed as crocidolite. Other varieties of amphibole asbestos, including richterite and potassian winchite, have been recognized but not used commercially (Wylie and Huggins 1980; Hodgson 1986). Chrysotile historically has been the most commonly used form of asbestos, followed by crocidolite, amosite, and then anthophyllite asbestos. Relatively small amounts of tremolite asbestos and actinolite asbestos have been produced and used.

PRODUCTION AND TRADE

Production

Asbestos has been mined for more than 4,000 years with evidence of its use as early as 2500 BC (Gross and Braun 1984). A small asbestos industry appeared in the early 1800s when the Italians established a textile manufacturing industry (Alleman and Mossman 1997). Use of asbestos did not increase significantly until after 1880 when large chrysotile deposits in Canada and Russia, and amosite and crocidolite deposits in South Africa, were discovered. The development of these deposits provided a large and steady supply of asbestos, allowing the asbestos industry to expand (Sinclair 1959; Selikoff and Lee 1978). This expansion, first observed in the

Table 1. Types of asbestos

Type	End Member Formulae
Actinolite asbestos	
Calcium magnesium silicate with varying amounts of iron	$\text{Ca}_2(\text{Mg}, \text{Fe}^{+2})_5\text{Si}_8\text{O}_{22}(\text{OH})_2$
Amosite (grunerite asbestos)	
Iron silicate with varying amounts of magnesium	$\text{Fe}^{2+}_7\text{Si}_8\text{O}_{22}(\text{OH})_2$
Anthophyllite asbestos	
Magnesium silicate with varying amounts of iron	$\text{Mg}_7\text{Si}_8\text{O}_{22}(\text{OH})_2$
Chrysotile	
Hydrated magnesium silicate	$\text{Mg}_3\text{Si}_2\text{O}_5(\text{OH})_4$
Crocidolite	
Complex sodium iron silicate (riebeckite) commonly called Blue Asbestos	$\text{Na}_2(\text{Fe}^{+2}_3\text{Fe}^{+3}_2)\text{Si}_8\text{O}_{22}(\text{OH})_2$
Tremolite asbestos	
Calcium magnesium silicate	$\text{Ca}_2\text{Mg}_5\text{Si}_8\text{O}_{22}(\text{OH})_2$

United States and then in Western Europe and the former Soviet Union, continued until about 1970 with few interruptions. The development of equipment to manufacture asbestos-cement pipe and sheet and the introduction of asbestos automobile brakes and clutches contributed to this rapid growth in the early 1900s.

During the early 1930s, however, there was a brief period of stagnation in world asbestos production that can be attributed mainly to the economic depression in the United States, which was the largest user of asbestos in the world. By 1935, world production increased as the U.S. economy began to recover (Figure 1). With the onset of World War II, production declined in most regions except Canada, South Africa, and the United States. U.S. war demands absorbed much of the increased production from these regions. Postwar reconstruction and expanding economies renewed the need for asbestos after the war and increased production of asbestos worldwide, which continued through the early 1970s. By this time, thousands of asbestos products were being produced in about 85 countries, and record asbestos production levels were achieved in many countries. At its peak around 1975, asbestos was mined in nearly 25 countries (Virta 2003).

Figure 1. Estimated world asbestos production from 1931 to 2002

In the early 1970s, growing opposition to the use of asbestos began to affect demand on a worldwide basis. Regulations became increasingly strict in most user countries, and liability started to become a major issue. Companies that mined asbestos, manufactured asbestos products, and, much later, installed or used asbestos products began to face an increasing number of class-action lawsuits (Anon. 2002). Compounding the legal problems was the shift from asbestos-based products to the use of asbestos substitutes or alternative products (e.g., ductile-iron or polyvinyl-chloride pipe instead of asbestos-cement pipe) in response to public opposition to the use of asbestos. As a result, the United States saw asbestos production decline from a peak of 136,000 t in 1973 to 2,720 t in 2002. Production of chrysotile in the United States stopped in 2002. World production experienced a similar decline from a peak of about 5.09 Mt (probably including sales of serpentinite waste from processing asbestos ore) in 1975 to 2.13 Mt in 2002 (Virta 2003). Table 2 breaks out production, by major producing countries, in 10-year intervals from 1900 to 2000.

About 174 Mt of asbestos was produced between 1900 and 2000, of which an estimated 167 Mt was chrysotile. About 2.8 Mt of amosite was mined during this time, nearly all from South Africa, which also produced most of the approximately 3.9 Mt of crocidolite mined in this period. Small amounts of crocidolite also were mined in Australia and Bolivia. An estimated 460,000 t of anthophyllite were mined between 1900 and 2000, mostly in Finland and the United States. Since 1900, small but unrecorded amounts of actinolite, anthophyllite, and tremolite asbestos have been produced in Bulgaria, India, Italy, Pakistan, Romania, South Africa, Turkey, and perhaps others. Figure 2 shows the production trends for all types of asbestos combined.

In 2002, almost all of the world's production of asbestos was chrysotile. Small amounts, probably less than a few thousand tons, of actinolite, anthophyllite, and tremolite asbestos are produced for local use in countries such as India, Pakistan, and Turkey (Hodgson 1986; Virta 2003). Russia led all producing countries, with 35.3% of the world's total asbestos production, and was followed, in descending order of tonnage, by China with 16.9%, Kazakhstan with 13.7%, Canada with 12.8%, Brazil with 9.8%, and Zimbabwe with 6.1%. In 2002, these countries accounted for 94.6% of world asbestos production, which was all chrysotile. Ten other countries also mined asbestos in 2002 (Table 3).

Production Localities

Historically, asbestos mining (almost all of which was chrysotile) was concentrated in relatively few areas. The same was true in 2002.

Three mines in Quebec, including the Jeffrey mine (until recently the world's largest chrysotile mine), accounted for all of the Canadian production of chrysotile. These mines are located near the towns of Asbestos and Thetford in a serpentinite belt that extends from eastern Canada to Alabama in the United States. Of historical note is that the Jeffrey mine scaled back its operations in 2002, with mining and processing occurring on a part-time basis to fill special orders. As the customer base has shifted away from the use of asbestos, production in Canada declined after peaking at about 1.7 Mt in 1973; in 2002, it was less than 250,000 t (USGS 1997–2004; Virta 2003).

In Russia, chrysotile continues to be produced near Asbest in the Bazhenovo District, east of Orsk in the Orenburg District, and near Ak-Dovurak in the Tuva District. The bulk of the production is from mines located in the serpentinites in the Ural Mountains. In Kazakhstan, asbestos is mined southwest of Kustanay in the Dzhetysay District. In 2002, combined production from Kazakhstan and Russia was much lower than in the 1980s. The reporting of major increases in production between 1998 and 2000 in Russia and 1998 and 2002 in Kazakhstan may have resulted from the inclusion of mill wastes used as crushed stone rather than from growing markets for asbestos fiber. Combined asbestos production in these two countries peaked at about 2.7 Mt in 1982 and about 1.04 Mt in 2002 (USGS 1997–2004; Virta 2003).

In China, chrysotile is mined in Hebei, Liaoning, Sichuan, Qinghai, and Xinjiang provinces. Mines in northwestern China account for more than 60% of China's asbestos production (Lu 1998). Most of China's asbestos is used in local industrial applications. Going against world trends, production in China has increased over time—from 150,000 t in 1975 to 360,000 t in 2002—because of rising internal demand for asbestos products (USGS 1997–2004; Virta 2003).

In Brazil, chrysotile is mined near Cana Brava. Lower than its peak production of 237,000 t in 1991, Brazilian production has remained relatively steady at a little more than 200,000 tpy for the past 5 years (Virta 2003).

In Africa, chrysotile is produced near Shabani in Zimbabwe. Production peaked at 279,000 t in 1979, declined to 115,000 t in 1999, but rebounded to 130,000 t in 2002. Production in South Africa, once a major producing country, peaked at 380,000 t in 1977 but was only 10,000 t in 2002. Until the early to middle 1990s, South Africa was the world's leading supplier of amosite and crocidolite. In 1992 and 1997, respectively, when it closed its amosite and crocidolite mines, worldwide production of amosite and crocidolite ended (Figure 3).

Industry Changes

Shifts in asbestos production among the major producing countries occurred over time as new deposits were developed, economies changed, armed conflicts occurred, and asbestos-related health risks became a major market influence. Italy was the leading supplier of asbestos until the late 1800s when the Canadian deposits were developed. During the first half of the century, Canada was the dominant producer, accounting for 60% to 90% of the world's production. By the 1950s, Kazakhstan and Russia (combined), South Africa, and Zimbabwe were beginning to produce significant quantities of fiber. These countries continued to increase their production through the early 1980s with the combined production of Kazakhstan and Russia becoming, and remaining today, the world's leading producing region of asbestos. China and Italy in the 1960s and Brazil in the 1970s rose from relative obscurity to become significant producers of asbestos. Since the 1980s, production has declined in all major producing countries, except for China, because of opposition to asbestos use (see Figure 3).

Figure 2. Estimated world production of chrysotile (A) and of amosite, anthophyllite, and crocidolite (B), from 1900 to 2000

Trade

Trade of asbestos also has shifted considerably throughout the 20th century. Until about 1950, the United States was the leading consumer of asbestos worldwide, using 37% to 99% of the world production annually between 1900 and 1950. For much of the 20th century, it was the leading importer of asbestos, mainly from Canada, South Africa, and Zimbabwe.

Canada, the principal producing country through much of the 20th century, supplied most of the asbestos (all chrysotile) used in U.S. markets. As other countries developed asbestos industries, Canada eventually became a major supplier of chrysotile to Asia, Europe, and South America. With the recent downturn in asbestos use in Europe and the United States, Canada's export focus has been to Southeast Asian countries.

By the 1940s, Kazakhstan and Russia (combined) had become a major exporter of chrysotile, supplying it to Eastern and Western Europe for decades, with smaller amounts being shipped to Asian countries. With the decline in asbestos usage in Western Europe since the late 1990s and significant declines occurring even in the former Soviet-bloc countries in Eastern Europe, export markets for Kazakhstan and Russia have declined.

South Africa was a major producer and supplier of asbestos (with more than 50% of production and sales being amosite and crocidolite) to the world. Prior to 1950, the United Kingdom and United States imported about 50% of South Africa's exports. Other important markets included Asia, the Middle East, and Europe. By the 1970s, however, South African export markets had shifted and Japan became the major importing country.

Zimbabwe is also a major world supplier of chrysotile. Its export markets were primarily in the United Kingdom through 1950, at which time the United States became a major consumer. Other export markets included Asia, Europe, and Latin America.

Several other producing countries supplied asbestos to world markets. Brazil exported worldwide but focused on South America and Caribbean countries. Cyprus, Greece, Italy, and Swaziland exported lesser amounts of asbestos to Africa, Europe, and Asia.

In general, the downturn in the asbestos industries of Europe and the United States after 1990 has caused a shift in major import markets to a few European countries (Belarus, Romania, and Spain) and Asia (India, Indonesia, Japan, the Republic of Korea, Thailand, and Turkey). Of these countries, India, Japan,

and Thailand are the leading consumers, dependent on imports for most of their manufacturing needs (Virta 2003).

GEOLOGY

Mineralogy

Chrysotile is a hydrated magnesium silicate with a chemical composition of $\text{Mg}_3\text{Si}_2\text{O}_5(\text{OH})_4$ and may contain small amounts of iron, manganese, and nickel, and trace amounts of aluminum. The compositions of the other common asbestos types, which are amphiboles, are more complex. Amphiboles are represented by the formula

where

A = Na and/or K

B = Na, Ca, Mg, Fe^{2+} , Mn, and/or Li

C = Al, Fe^{2+} , Fe^{3+} , Ti, Mg, Mn, and/or Cr, and

T = Si and/or Al.

The composition of chrysotile and the common amphibole asbestos varieties are given in Table 1, with only the major cations listed (Whittaker 1979; Wicks 1979; Zussman 1979; Hodgson 1986; Skinner, Ross, and Frondel 1988; Leake et al. 1997). Leake et al. (1997) provide a detailed breakout of the amphibole varieties by chemistry, identifying specific compositional ranges of each.

The basic building block of asbestos fibers is the silicate tetrahedron, which typically occur as sheets ($\text{Si}_4\text{O}_{10}^{4-}$ in chrysotile and double chains ($\text{Si}_4\text{O}_{11}^{6-}$ in the amphiboles (Figure 4). The sheets and chains have an overall negative charge so cations as well as hydroxyl units (OH^-) are sandwiched between the sheets in chrysotile and chains in amphiboles to balance out the ionic charge in the structures (Deer, Howie, and Zussman 1966; Skinner, Ross, and Frondel 1988; Frondel 2001).

Owing to a mismatch of the dimensions of the cation layer (composed of $\text{Mg}[\text{OH}]_2$ structures, also called the brucite or octahedral layer) with the silicate layer (Si_2O_5 or tetrahedral layer) in chrysotile, the sheet spirals into an extremely thin fiber having an average diameter of approximately 25 nm (Figure 5, note end structures). Slight variations in the crystal structure result in the formation of three chrysotile polytypes: clinochrysotile, orthochrysotile, and parachrysotile (Wicks 1979; Hodgson 1986).

The structure of the amphiboles consists of two chains based on Si_4O_{11} units separated by a band of seven cations with two

Figure 4. Single silica tetrahedral chain that is the basis for the double-chain-width structure of amphiboles and the multiple-chain-width structure of sheet silicates

Adapted from Hodgson 1986.

Figure 5. Spiraling sheet structure of chrysotile fibrils

hydroxyl groups attached to the central cation of each unit cell. These are often called I-bars because of their shape in cross section. These stack together to form the final structure, with a marked cleavage developed between the ribbons (Figure 6). Under the conditions in which amphibole asbestos forms, crystal growth is preferential in the direction of the chain length, resulting in amphibole fibers that are long and thin (Ross 1981).

Physical Properties

Asbestos fibers are characterized by high tensile strength, flexibility, resistance to chemical attack and thermal degradation, large surface area, and ability of some varieties to be woven. Each type of asbestos has different physical characteristics, as do the same asbestos types from different sources (Sinclair 1959; Zussman 1979).

Chrysotile is a white, fibrous material. The fibers are extremely thin, and most are soft and flexible enough to be woven. Individual chrysotile fibers have diameters ranging from 25 nm to 50 nm (Yada 1967). Commercial grades of chrysotile have lengths ranging from a fraction of a millimeter to several centimeters (Badollet 1951). Chrysotile fiber bundles can have lengths of 5 cm (Selikoff and Lee 1978). Most of the chrysotile fibers used commercially are shorter than 1 cm. Bundle widths can be several millimeters (Virta 2002). There are fundamental differences in fiber lengths of chrysotile from different deposits. In commercial samples defiberized in suspension

Figure 6. Amphibole structure showing the octahedral cation layer sandwiched between the silicate double chains perpendicular to the C axis

using an anionic surfactant, average chrysotile fiber lengths were 4.0 mm for a Kaapsche Hoop sample (South Africa), 1.8 mm for a Cassiar sample (British Columbia, Canada), 1.4 mm for a Bell mine sample (Quebec, Canada), and 0.6 mm for a Shabani sample (Zimbabwe) (Hodgson 1986).

Tensile strength measurements on asbestos correspond to the strength of fiber bundles rather than individual fibers. Consequently, there is a wide variation in reported values. Data summarized by Hodgson (1986) show the tensile strength of chrysotile to be between 1,107 MN/m² (meganewtons per square meter) and 4,400 MN/m², making it one of the stronger asbestos types. Tensile strength increases slightly when heated until thermal degradation occurs (Bryans and Lincoln 1971; Hodgson 1986).

Because chrysotile is heat resistant, it is used routinely in commercial products that may be exposed to temperatures exceeding 700°C. Around 90°C, chrysotile begins to lose adsorbed water. Dehydroxylation (loss of the OH⁻ in the structure) begins at 640°C and is complete by 810°C. Above 810°C, the chrysotile structure begins to transform into forsterite and silica. These reactions are affected by sample preparation and impurities in the sample (Deer, Howie, and Zussman 1966; Hodgson 1986). The fusion temperature for chrysotile is 1,521°C (Badollet 1951).

Chrysotile has an extremely large surface area, on the order of 13 to 18 m²/g because of its fibrillar structure. Fiberizing the samples has little effect on the measured surface area of chrysotile, which suggests easy penetration of the fiber bundles by gases regardless of the degree of fiberization (Hodgson 1986).

Amphibole asbestos fibers generally are harsher and more brittle than those of chrysotile. They also are more resistant to chemical attack, have very high filtration rates, have a greater hardness (4 to 6 on the Mohs scale), and are comparatively long, ranging up to several inches (Table 4). Their color ranges from white for tremolite through yellowish-brown for amosite to lavender or blue for crocidolite (Badollet 1951). Tensile strengths range from 303 MN/m² for a tremolite asbestos from Pakistan to about 3,089 MN/m² for a crocidolite from South Africa (Aveston 1969; Hodgson 1986). All of the forms of amphibole asbestos withstand temperatures exceeding several hundred degrees Celsius without degradation. The fusion temperature for all of the asbestiform amphiboles exceeds 1,224°C. Their resistance to attack by acids and bases ranges from fair for actinolite asbestos to very good for anthophyllite asbestos (Badollet 1951).

Table 4. Properties of asbestos fibers

Property	Actinolite Asbestos	Anosite	Anthophyllite Asbestos	Chrysotile	Crocidolite	Tremolite Asbestos
Structure	Reticulated long prismatic crystals and fibers	Lamellar; coarse to fine fibrous and asbestiform	Lamellar; fibrous asbestiform	Usually highly fibrous fibers; fine and easily separable	Fibrous in ironstones	Long; prismatic and fibrous aggregates
Mineral association	In limestone and in crystalline schists	In crystalline schists, etc.	In crystalline schists and gneisses	In altered peridotite adjacent to serpentine and limestone; near contact with basic igneous rocks	Iron-rich siliceous argillite in quartzose schists	In Mg limestones as alteration products of highly magnesian rocks; metamorphic and igneous rocks
Origin	Metamorphic	Metamorphic	Metamorphic	Metamorphism of basic igneous rocks	Regional metamorphism	Metamorphic
Veining	Slip or mass fiber	Cross fiber	Slip or mass fiber	Cross and slip fibers	Cross fiber	Slip or mass fiber
Essential composition	Ca, Mg, Fe silicate with some water	Fe, Mg silicate with some water	Mg silicate with some iron	Mg silicate with some water	Na, Fe silicate with some water	Ca, Mg silicate with some water
Crystal system	Monoclinic	Monoclinic	Orthorhombic	Monoclinic	Monoclinic	Monoclinic
Color	Greenish	Ash gray or brown	Grayish white; brown-gray or green	White, gray, green	Lavender blue, metallic blue	Gray-white, greenish, yellowish, bluish
Luster	Silky	Vitreous; somewhat pearly	Vitreous to pearly	Silky	Silky to dull	Silky
Hardness	6±	5.5–6.0	5.5–6.0	2.5–4.0	4	5.5
Specific gravity	3.0–3.2	3.1–3.25	2.85–3.1	2.4–2.6	3.2–3.3	2.9–3.2
Optical properties	Biaxial negative, extinction inclined	Biaxial positive, extinction parallel	Biaxial positive, extinction parallel	Biaxial positive, extinction parallel	Biaxial ±, extinction parallel	Biaxial negative, extinction inclined
Refractive index	1.63 ± weakly pleochroic	1.64 ±	1.61 ±	1.51–1.55	1.7 pleochroic	1.61±
Length	Short to long	51 to 280 mm; varies	Short	Short to long	Short to long	Short to long
Texture	Harsh	Coarse but somewhat pliable	Harsh	Soft to harsh; also silky	Soft to harsh	Generally harsh; sometimes soft
Specific heat, J/kg/°K	505	449	488	619	468	493
Tensile strength, kN/m ²	6,895 and less	110,316–620,528	27,579 and less	551,581–689,476	689,476–2,068,427	6,895–55,158
Temperature at maximum ignition loss, °C	na*	871–982	982	982	648	982
Filtration properties	Medium	Fast	Medium	Slow	Fast	Medium
Electric charge	Negative	Negative	Negative	Positive	Negative	Negative
Fusion point, °C	1,393	1,399	1,468	1,521	1,229	1,316
Spinnability	Poor	Fair	Poor	Very good	Fair	Poor
Resistance to acids and alkalis	Fair	Good	Very good	Poor	Good	Good
Mineral impurities present	Lime, iron	Iron	Iron	Iron, chrome, nickel, lime	Iron	Lime
Flexibility	Poor	Good	Poor	High	Good	Poor
Resistance to heat	na	Good; brittle at high temperatures	Very good	Good; brittle at high temperatures	Poor, fuses	Fair to good

Adapted from Skinner, Ross, and Frondel 1988.

Amphiboles have a surface area of 2 to 9 m²/g, which increases with fiberization. This is not true, however, for chrysotile asbestos (Addison, Neal, and White 1966; Hodgson 1986).

Amphibole fibers generally are more variable in width and less symmetrical than chrysotile fibrils. Franco et al. (1977) examined samples of crocidolite with fiber widths ranging from 50 to 150 nm, although widths up to 350 nm also have been reported for other samples (Wylie 1979). Lengths of fiber bundles up to 8 cm for crocidolite and 30 cm for amosite have been described (Selikoff and Lee 1978).

Chemical Properties

Ideal compositions (Table 1) frequently are different from those observed in deposits. Chrysotile fibers normally contain mineral impurities, including, commonly, magnetite, which accounts for higher than normal iron concentrations. Other minerals that may be present include brucite, calcite, and chrochite (Hodgson 1986). Skinner, Ross, and Frondel (1988) reported analyses for chrysotile from Canada, Swaziland, the former Soviet Union, and Zimbabwe. They found that SiO₂ content ranged from 38.75% to 39.93%, MgO ranged from 38.22% to 40.30%, FeO ranged from 0.45% to 2.03%, and Fe₂O₃ ranged from 0.10% to 1.59%. Hahn-Weinheimer and Hirner (1977) reported the average composition of 28 chrysotile samples from Quebec and Newfoundland as 42.123% SiO₂, 41.868% MgO, 0.48% FeO, and 1.357% Fe₂O₃. They also reported 0.418% Al₂O₃, 0.019% CaO, 0.004% CoO, 0.006% Cr₂O₃, 0.052% MnO, 0.087% NiO, 0.002 TiO₂, and 13.8% H₂O⁺.

The ideal and observed compositions for asbestiform amphiboles often differ because cations are easily substituted for one another in the A, B, and C sites in the amphibole crystal structure. This results in a wide range of compositional variations. Using the nomenclature developed by the International Mineralogical Association, amphiboles are categorized as (1) magnesium-iron-manganese-lithium, (2) calcic, (3) sodic-calcic, and (4) sodic, encompassing about 75 amphibole end members (Leake et al. 1997). The complexity of amphibole nomenclature is pertinent to the asbestos issue in that current asbestos regulations specifically mention actinolite asbestos, amosite (grunerite asbestos), anthophyllite asbestos, crocidolite (riebeckite asbestos), and tremolite asbestos. Wylie and Verkouteren (2000) and Meeker et al. (2003) identified asbestiform varieties of magnesioriebeckite, richterite, tremolite, and winchite in a vermiculite deposit in Libby, Montana. Meeker et al. (2003) further indicated that edenite and magnesioarfvedsonite may also be present in low concentrations. These asbestiform minerals had been identified as soda tremolite, richterite, soda-rich tremolite, and tremolite asbestos in past studies (Larsen 1942; Nolan et al. 1991). So, although only five forms of amphibole asbestos are recognized by regulatory agencies, other amphibole varieties may possess a fibrous

or asbestiform habit. Table 5 lists compositions for the major amphibole asbestos varieties.

Chrysotile has a surface charge that can be positive or negative depending on its source. Most chrysotile has a positive charge, reflecting the net positive charge of the (MgOH)⁺ layer on the outer surface layer of the fiber. Fibers from which weathering has removed the (MgOH)⁺ layer, exposing the silica-rich layer below, have negative charges. The size and sign of the charge also change when the fiber is suspended in solutions of different pH and composition. Ions in the solution may be adsorbed onto the fiber's surface, changing the surface charge (Chowdhury and Kitchener 1975; Hodgson 1986). Zeta potentials for chrysotile range from 13.6 mv to 54 mv for selected samples (Chowdhury and Kitchener 1975; Hahn-Weinheimer and Hirner 1977). Treatment of chrysotile with acid removes (MgOH)⁺ layers, mimicking weathering, and produces a negative surface charge, which ranged to -16.6 mv for a sample from Dzhetysay District in Kazakhstan (Gracheva 1972; Chowdhury and Kitchener 1975).

The surface charge for asbestiform amphiboles is negative with zeta potentials ranging from -10 mv to -40 mv for selected samples (Ralston and Kitchener 1975; Hodgson 1979). The negative charge is attributed to the silica-rich layers exposed on the fiber surface.

The isoelectric point or pH for zero potential for chrysotile ranges from 10.5 to 11.3, depending on the source of the fiber and the method of measurement. Chrysotile flocculates from solution when its isoelectric point is reached. Amphiboles, however, maintain their strongly negative surface charge at higher pH levels and remain dispersed under conditions that cause chrysotile to flocculate. These properties were used to advantage in highly alkaline cement mixes where the amphibole fibers, not being flocculated, helped to disperse the chrysotile, which would normally have flocculated in the cement mix (Hodgson 1986). The isoelectric points for several amosite and crocidolite samples examined were between 2.2 and 4.0 (Prasad and Pooley 1973).

Asbestos often is used in chemical applications where resistance to chemicals is of paramount importance. Table 6 gives data on the effect of various acids and caustic soda on asbestos after long exposure at room temperature and for short exposure at boiling temperatures. Strong acids aggressively attack chrysotile, which is resistant to 25% caustic but is attacked by strong caustic (70%) at its boiling temperature (Badollet 1951).

Most amphibole fiber varieties are more acid resistant than those of chrysotile. They are not entirely acid resistant, however, and can exhibit weight losses of 2% to 23% through dissolution when exposed to concentrated acids at higher temperatures. Because of their higher iron contents, actinolite and amosite exhibit greater weight loss when exposed to acids than do the other amphibole asbestos varieties (Hodgson 1979, 1986).

Table 6. Solubility of asbestos

Type	Percent Loss in Weight, Refluxing 2 hr, 25% Acid or Caustic				
	HCl	CH ₃ COOH	H ₃ PO ₄	H ₂ SO ₄	NaOH
Actinolite	20.31	12.28	20.19	20.38	9.25

† Iron changing in weight as the result of oxidation.

Higher temperatures also cause other physical changes in asbestos. Besides dissolution of the fiber in boiling acids, weight can also change through water loss. Higher temperatures evaporate adsorbed water first and eventually result in the loss of structure water (OH⁻). The weight loss for the amphiboles is considerably less than that for chrysotile because much less OH⁻ is available to be driven off as water. Weight losses for different types of asbestos when heated for 2 hr at successive temperatures from 204° to 982°C are shown in Table 7 (Badollet 1951; Badollet and Streib 1955).

Table 8 shows the effect of heating on the tensile strength of Canadian chrysotile fiber. The fiber bundles tested were very small so that the heat transfer would be completed in the 3-min heating time. Even after heating at 648°C, chrysotile retained 32% of its strength (Badollet 1951).

Table 8. Effect of heat on tensile strength of Canadian chrysotile fiber

	Tensile Strength, kN/m ²	Percent of Original Tensile Strength
Original crude, no heat	903,000	100.0
Heated 3 min at 316°C	827,000	91.6
Heated 3 min at 427°C	662,000	73.3
Heated 3 min at 538°C	538,000	59.5
Heated 3 min at 649°C	290,000	32.0

Principal Deposits

Major asbestos deposits occur in mountain chains of all ages where widespread metamorphism has occurred (Figure 7). Deposits in the Urals, the Appalachians, and the Rocky Mountains are classic examples.

Origin and Modes of Geologic Occurrence

The host rock for most of the world's chrysotile production is ultrabasic in composition (Keith and Bain 1932; Berger 1963; Bates 1969; Whittaker 1979)—categorized as Type I or Type II deposits. Type I deposits occur in alpine-type ultramafic rocks, including ophiolites and serpentinites. Type II deposits can be found in stratiform ultramafic intrusions. The remaining chrysotile production is derived from serpentinized dolomitic limestone, or Type III deposits. Amosite and crocidolite are found in metamorphosed ferruginous sedimentary formations, or Type IV deposits, which include banded ironstones, ferruginous quartzites, and iron-rich silicified argillite (Ross and Virta 2001). Tremolite asbestos and anthophyllite asbestos are associated with metamorphosed ultrabasic rocks.

The geologic age of asbestos deposits ranges greatly from earliest Precambrian in Zimbabwe and Swaziland to Upper Jurassic in California. The Ontario, Ungava, and Brazil deposits are Precambrian. Deposits of the Eastern Townships, Vermont, and Newfoundland are Mid-Paleozoic in age and are associated with

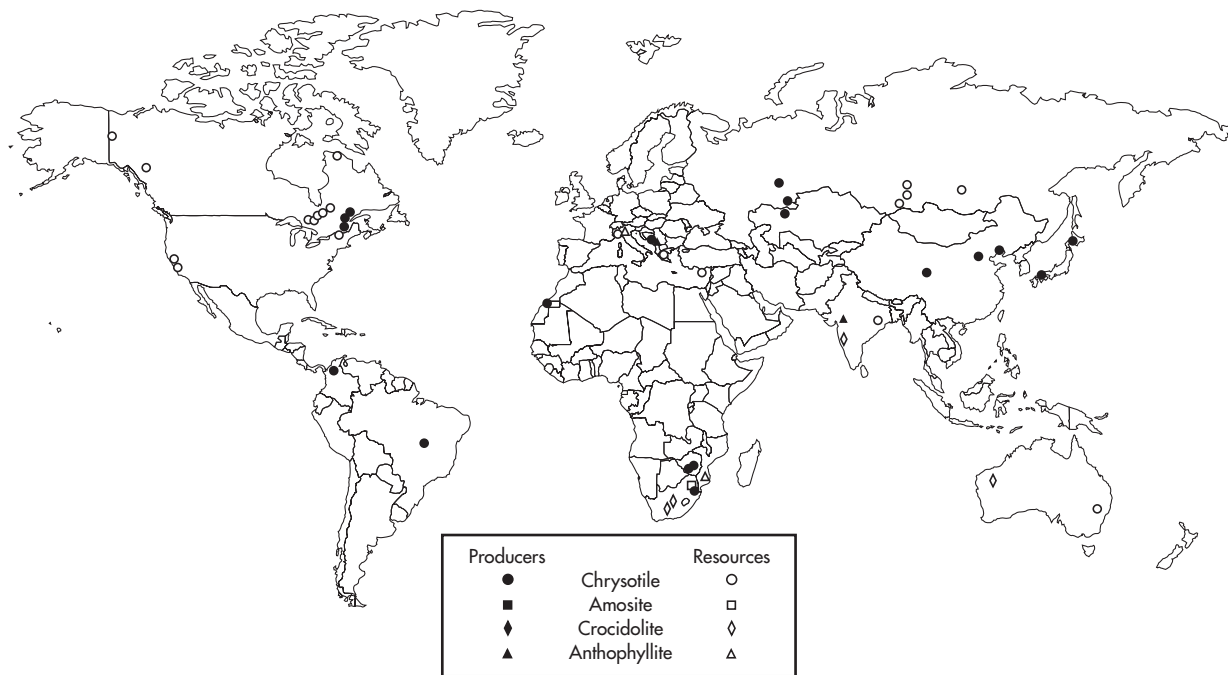

Figure 7. World asbestos deposits

early folding in the Appalachian mountain belt. The deposits of western Canada are associated with mountain building during the Late Paleozoic, while the deposits in Kazakhstan and Russia range from Early Paleozoic to Late Paleozoic or Triassic in age.

Structures

Faulting, folding, or shearing played a major role in the formation of chrysotile deposits in altered ophiolite sequences (Cooke 1937; Lamarche and Wicks 1975). The basic sequence followed was (1) serpentinization of ultramafic rocks; (2) compression associated with volume increase and tectonic collisions resulting in thrust faulting, shearing, more serpentinization, and formation of chrysotile; and (3) release of compression resulting in gravity faulting, jointing, and brecciation; followed by succeeding cycles. The introduction of swarms of small intrusive dikes of acidic to intermediate composition also contributed to the fracturing and opening of the rock. Fracturing, in turn, led to serpentinization and the formation of chrysotile fiber.

Most chrysotile ore deposits are found in serpentinized peridotitic rather than in dunitic host material. It is believed that the serpentinized dunitic bodies tend to flow when subjected to stress, thereby aiding in the development of fracturing in the surrounding, more brittle peridotitic bodies.

Asbestos Veining

Chrysotile asbestos is referred to as *cross fiber* when the fibers lie transverse to the vein, and as *slip fiber* when the fiber lies in the plane of the vein (Cooke 1937; Gold 1967; Whittaker 1979). The orientation of cross-fiber chrysotile ranges from normal to sharply inclined to the vein walls. When sharply inclined, it is referred to as *oblique fiber*. The fiber in cross-fiber and slip-fiber veins may be straight, gently curved, or contorted. Fiber containing sharp flexures is apt to break easily.

Partings are present in many of the veins, either as microscopic discontinuities or as irregularly shaped inclusions composed

of picrolite, serpentine, brucite, and magnetite, or combinations of these. The veins may be relatively persistent or short and lenticular, in the form of stockworks or in parallel systems known as ribbon fiber. They may be fissure fillings, replacements, or stress-relief features, and many are the result of a combination of these processes. Some very short fiber is derived from a variety referred to as mass fiber. Mass fiber consists of either the complete replacement of most of the original mineral constituents by fiber, each grain of which has a different fiber orientation, or by a dense network of fine, reticulating replacement veins. Both varieties result in a very high content of short fiber, and the rock, which appears to be largely fibrous, is sometimes referred to as "fur rock."

Chrysotile Deposits in Ultrabasic Rocks in North America

Ultrabasic deposits encompass the Type I and Type II deposits. Accounting for about 90% of the world production of asbestos, Type I deposits generally contain cross- or slip-fiber veins (Ross and Virda 2001). Examples of these types of deposits occur throughout the world. Typical are the chrysotile deposits in the Eastern Townships, Quebec, Canada, which occur along a major serpentine belt that arcs northeastward into the Gaspé Peninsula and southward into the Appalachian mountain belt of Vermont.

Most of the major deposits are located along a region 90 km long that lies parallel to and 80 km southeast of the St. Lawrence River. The region extends from a point near East Broughton, Quebec, southwestward past Thetford Mines and Black Lake to Asbestos and Danville.

This serpentine belt is a typical ophiolitic complex of gabbroic and dioritic rocks, and of serpentinized pyroxenite, peridotite, and dunite. The complex is associated with granitic, rhyolitic, and talc-carbonate rocks and is a partially serpentinized ultrabasic intrusive emplaced in the crust along faulted zones of weakness. It may have been extruded onto, or just under, unconsolidated aluminous and siliceous sediments in a eugeosyncline ocean basin. Magmatic differentiation within the ultramafic magma is thought to have been

responsible for the formation of the various pyroxenite, peridotite, and dunite phases found in the complex. Chrysotile formed mainly in highly serpentinized peridotite (harzburgite containing 10% to 15% enstatite) and is found in numerous places along the strike of the complex. The complex is believed to have been a submarine extrusive, simplifying the explanation of the source of water for serpentinization, the allowance for large volume change, the presence of fiber as open fracture fillings in stockworks, and the banded fiber in ribbon zones. It also explains the presence of pillows, most of which are gradationally serpentinized from the surface inward (Yamarche and Riordon 1981).

Another example is the Shabani deposit, situated about 160 km east of Bulawayo, Zimbabwe. This deposit is renowned for its low iron content, resulting from the low concentration of magnetite in the fiber, and its long fiber length (Bowles 1959). The deposit lies near the base of a lenticular ultrabasic sill, which is 14 km long and 2 to 5 km wide and intrudes Early Precambrian gneisses. The sill, which strikes northwest and dips about 40° SW, is composed of dunite at the base, overlain by peridotite, pyroxenite, and gabbro. A swarm of younger diabase dikes cuts the ore zone. Strong zones of shearing, both parallel and oblique to the basal contact, truncate the dikes. The intrusion and shearing have caused strong serpentinization of the dunite and heavy talc-carbonate alteration, particularly along the footwall shear zone. The fiber is present as a stockwork of cross-fiber veins described as stress-controlled dilation seams. The quality is good, and the length of the fiber is as much as 38 mm in places (Laubscher 1964, 1968; Oldham 1968; Wilson 1968).

A third example of chrysotile in ultrabasic rock is near Coal-inga, California. Unlike the previous two examples, the Coalinga deposit is a mass fiber deposit of chrysotile. Instead of the fiber being present in veins as cross or slip fibers, it is distributed throughout the entire rock mass. The deposit is an ultrabasic intrusive that trends northwestward, covers an area about 20 km long and 5 to 8 km wide (Munro and Reim 1962), and intrudes into Jurassic sediments in Late Jurassic or Early Cretaceous times. It is a highly sheared serpentinite with abundant slickensides, and the ore is extremely platy. Boulders of massive serpentinized material are scattered throughout the loose platy serpentine. Landslides, for which there is evidence, may have contributed to the extreme deformation of the serpentine. The ore contains abundant short chrysotile fiber.

Chrysotile Deposits in Dolomite

In addition to the large deposits of chrysotile asbestos found in serpentinized peridotite, comparatively small tonnages are mined from Type III, or serpentinized dolomitic limestones (Hall 1930; duToit 1946; Pelletier 1964; Van Biljon 1964; Rowbotham 1970). Much of such fiber is of high quality and free of the magnetite that is commonly associated with most deposits of ultrabasic origin.

Chrysotile of this type was mined in the Carolina District in the Transvaal, South Africa, and in the Salt River and Sierra Ancha regions in Arizona, United States. The Arizona deposits, approximately 60 km northeast of Globe, are tabular in shape and are in a serpentinized dolomitic limestone formation. Serpentinization occurred during the intrusion of diabase sills. Chrysotile is found in thin discontinuous veins. The fiber ranges from harsh to soft and from a few millimeters to several centimeters long. Unlike the ultrabasic deposits, the Globe deposit is relatively free of magnetite (U.S. Bureau of Mines 1945; Li 1975).

Crocidolite and Amosite Deposits

Examples of Type IV deposits occur in South Africa, where crocidolite and amosite are found in deposits known as banded iron-

stones, ferruginous quartzites, or iron-rich silicified argillites (Hall 1930; duToit 1946; Frankel 1953; Cilliers et al. 1961; Keep 1961; Cilliers, Le, and Genis 1964; Pelletier 1964; Dreyer and Robinson 1981). Cross-fiber veins are present as closely spaced ribbons roughly conformable with the bedding, which in some localities is distorted and dips steeply. Most crocidolite veins are less than 50 to 80 mm thick, and most of the fiber is between 6 to 19 mm in length. Amosite veins commonly are 250 to 300 mm thick.

Crocidolite is found over a large area of Cape Province in a belt of the Lower Griquatown series of the Transvaal system. Crocidolite and amosite are found in similar formations in the vicinity of Pietersburg in northern Transvaal. In some places, the two varieties are side by side in the same vein. A vein composed of crocidolite at one end and amosite at the other is called a doublet. In the Pietersburg Area, a silky, dusty blue variety of amosite called montasite, sometimes confused with crocidolite, has been found.

An amosite-bearing banded ironstone formation crops out for a distance of more than 30 km near Penge in the Lydenburg District of the Transvaal. The fiber-bearing banded ironstones and associated sedimentary members dip southwestward at about 20°. Thin, persistent sills of dolerite that are conformable with the bedding have intruded this sequence. Mapping in the Transvaal region revealed that the deposits were located on the loci of intersections of anticlinal or synclinal structures generated by superimposed north- and east-trending folds. Similar patterns of cross-folding were observed in many crocidolite deposits in the Northwest Cape and elsewhere.

Anthophyllite, Tremolite, and Actinolite Deposits

Of the countries in which anthophyllite asbestos deposits are known, Finland was formerly the most important producer with major deposits at Paakkila in the parish of Tuusniemi in eastern Finland and Maljasalmi in Kuusjarvi Parish. The Finnish anthophyllite asbestos deposits were a series of lenses of amphibolitized and serpentinized ultrabasic material, which appeared to have become detached from larger bodies during an early period of severe deformation. The serpentinized amphibolite lenses were in a biotite gneiss that had been intruded by Late Karelian granites and pegmatite (Aurola 1954; Ross and Nolan 2003).

Anthophyllite asbestos is found near Greenmountain in Yancey County, North Carolina. Most of the deposits, which are associated with altered peridotites and pyroxenites, consisted of mass fiber, although cross and slip fibers are more common in other parts of the state. Similar material has been found in the nearby state of Georgia (Conrad, Wilson, and Allen 1963).

Italy has produced some long-fiber tremolite from small deposits at Val Malenco, in the Sondrio District 100 km north of Milan. Tremolite fiber has also been found in the Aosta District north of Turin in the Italian Alps.

Amphibole asbestos also has been found in Bulgaria, India, Romania, Taiwan, Turkey, and the former Yugoslavia. Most of the Indian production is from Rajasthan. Although some deposits of fibrous actinolite have been reported, production is extremely small.

TECHNOLOGY

Exploration Techniques

Geophysical

Where there are few outcrops of asbestos-bearing ultrabasic rocks, aeromagnetic and ground magnetic surveys are employed in the early stages of exploration (Low 1951; Conn 1967). Ground magnetic surveys may be used to check and define in more detail

anomalies obtained by an airborne survey of a large area. If the area for exploration is small, the ground survey may be used by itself.

Magnetic surveys are used to locate ultrabasic bodies and define potential ore deposits because of their association with secondary magnetite formed during extensive serpentinization. Many asbestos deposits in ultrabasic rocks contain more magnetite than does barren serpentine.

Diamond Drilling

Diamond drilling is used to assess and define the limits of an asbestos deposit. Because most asbestos ore bodies are large, it is customary to drill vertical holes on a grid pattern. In the first stages of exploration, a wide interval (often 61 m) is used. When an asbestos-bearing zone is encountered, a narrower interval is used. If a deposit is elongated in one direction, holes are spaced at closer intervals across the strike. Narrow, tabular ore bodies are explored using angled holes to give the attitude and true thickness of the body.

Preliminary drill holes are used to determine whether or not the fiber has a preferential vein angle. If the angles of the vein intersections appear random, no changes are made to the drilling program. If the deposit exhibits prominent vein angles that diverge from the average 45°, the attitude of all later drill holes are corrected for this variation.

When drilling is impractical, trenching or the use of adits or shafts and lateral workings may offer the only means of assessing a deposit.

Evaluation of Deposits

Evaluation

An asbestos deposit is evaluated on size, fiber yield or grade, and quality of fiber (Dean and Mann 1968; Conn and Mann 1971; Stewart 1981). Although the size of a mineral zone is established using geophysical or drilling techniques, yield and quality of fiber are evaluated through laboratory and visual methods. The simplest method for determining yield is visual, using drill core sections. Each vein of cross fiber is recorded and the vein width is measured and recorded in multiples of 1.6 mm. Because many veins are of irregular width, an average vein width is used. Allowances also are made when veins contain partings or the fiber is kinked (which causes the fiber to break into shorter lengths than the vein width), or the fiber is sharply inclined to the vein walls (in which case the vein width is smaller than the fiber length). To estimate fiber yield, the total drill core length is divided into the sum of the average vein widths in the core section. As an example, each 1.6-mm vein of fiber in a 1.5-m section corresponds to about 0.1% fiber in the rock.

Because it is not easy to determine the slip-fiber length by the normal visual methods of logging core, laboratory assistance usually is required.

Fiber Value Determination. After the fiber yield of the ore is determined, the value of the fiber and the value of the ore in dollars per ton are estimated. The fiber is graded using the Quebec Standard (QS) Test developed by the Quebec Asbestos Mining Association (QAMA; see Table 9; Asbestos Textile Institute and QAMA 1975). This test is performed on the QS testing machine, which consists of a stack of three sieve boxes with 12.7-mm (½-in.), 4-mesh-per-inch, and 10-mesh-per-inch screens, stacked top to bottom, and a bottom box serving as a pan. Exactly 454 g of asbestos fiber is placed in the top sieve, and the stack of sieves is shaken using a rotary shaker. The weight of fiber on each screen and the bottom pan is determined.

* As of 2003, the grading standards had not been converted to the metric system.

Multiplication factors are applied to the weight in each size fraction, giving a total point score for the sample. Comparing the point score to a graph of point score versus fiber value, which was previously developed for this or similar deposits, determines the average fiber value.

If extraction of the fiber is not done, average fiber value can be approximated on drill cores or face readings. The average vein widths (assumed to equal fiber length) are measured in the drill core or working face. These lengths are sorted into the QS Test screen-size categories. To estimate the fiber fraction in each category, the total length of fiber measured is divided into the total fiber length contained in each QS Test size category. As an example, if the sum of the vein widths measured in a drill core is 57.2 cm and vein widths (assumed to equal fiber lengths) in the +12.7 mm QS Test size category totals 16.5 cm, this size category represents 29% of the total measured fiber length. By multiplying 29% by 454 g, the weight of asbestos fiber used in a QS Test, it is estimated that the +12.7-mm size fraction represents a weight of about 132 g. These calculations are repeated for the other QS Test size categories. Once the weight in each QS Test size fraction is approximated, the procedure previously discussed—using multiplication factors and graphs of point score versus fiber value—is used to estimate average fiber value.

In both of the previous cases, the fiber value must be converted into a dollar-per-ton value, so the yield also must be calculated. As described, the total length of the core section or face measured is divided into the total measured fiber length to determine the percent yield per ton of ore. For example, 57.2 cm of measured fiber in a 25.9-m drill core represents a yield of 2.2%. A correction is made for the average vein angle in the deposit, assumed to be 45° in this example. The corrected yield is equal to 2.2% divided by the $\sin 45^\circ$, or 3.1%. If the average fiber value was determined to be \$400/t, the indicated ore value is calculated to be 3.1% of \$400, or \$12.40/t.

Face Readings

On the surface or in underground workings, channel sampling may be employed. One method is to take a linear reading along either wall of a drift or crosscut. Another method involves taking cross sections at intervals of 1.5 m along the back and both walls to ensure that veins running parallel to the drive are not excluded. Because the rock tends to break along fault planes, it is difficult to obtain representative results.

Bulk Sampling

Because the various methods of logging and sampling seldom give entirely dependable results, bulk sampling is the most accurate means of determining yield, fiber value, and ore value. Even bulk sampling, however, can give an appreciably higher fiber value than that obtained in a commercial mill, because it is not easy in the laboratory to simulate the conditions of an operating mine and mill. From the time of blasting to the final product, the fiber is subjected to a good deal of handling under real operating conditions. Some handling is rather severe, and breakage of fibers can occur.

Bulk sampling often is used as a means to arrive at a suitable factor to be applied to drill-core data, as described with the multiplication factors and point-score-value graphs. The sampling may be done by diamond-drilling a block of ground at close intervals prior to mining and milling. The cores can be read visually and then milled. If precautions are taken to avoid contamination and the sample is sufficiently large, results should be reasonably reliable despite the erratic distribution of fiber in the rock.

Tensile Strength

In the preceding paragraphs, measurements and evaluations are based entirely on the length of the fiber. For many applications, the fiber is valued for the strength it lends to the product. Strength evaluations should include tests on the product made with the subject fiber.

Tonnage and Grade

To estimate the tonnage and grade of a deposit from diamond drill-core data, individual drill holes may be weighted according to their intervals by using the polygonal method. An alternative procedure is to use cross sections, or groups of cross sections and, by weighting the individual holes in each section, determine the average grade for each section.

A third method employs contoured cross sections, which is based on a reasonable interpolation of the intervening area between drill holes. This method permits the estimator to make use of all available geological information in his interpolation. In open-pit operations, contoured horizontal sections corresponding to expected mine level intervals may be prepared and can serve as a useful guide to mining. Separate horizontal sections contoured for rock value and fiber value per ton permit the mine operator to produce a more balanced mill feed with respect to both fiber content and grades.

Mining

Chrysotile mining developed through a succession of mining practices and equipment. Originally, the simplest hand methods were employed in shallow open-pit workings. Later, when pits reached considerable depth, overhead cableway derricks were used. Now, power shovels and heavy-duty trucks have replaced other loading and transporting equipment for open-pit quarry methods.

In its early history, most chrysotile was mined in Canada using underground methods, which included glory holes, shrinkage and sublevel stoping, and block caving. Now open-pit mining prevails. Surface mining offers advantages in recovery, grade control, economy, and safety. The shift to open-pit mining resulted mainly from the introduction of large-capacity power shovels, trucks with higher payload capacities, improved rock-drilling equipment, and new blasting agents and techniques.

In Africa, chrysotile is still mined underground. Most ore bodies are tabular in shape with a pronounced dip so that the economic limit for quarry mining is reached at a comparatively early stage. Ore widths in the larger mines commonly range from 20 to 60 m and as much as 120 m. Some ore bodies, notably in the Shabani District of Zimbabwe, are long. In one case, development extended for 5 km along the strike and was being developed or diamond drilled to more than 300 m in depth.

Several underground methods have been used. Sublevel stoping and caving may be initiated by blasting holes drilled upward from sublevel crosscuts, starting first on the hanging-wall side and retreating over a considerable width toward the footwall. Development and retreat also may be along the strike of the ore. In some cases, high pressures tend to develop from an arching effect. These pressures can be released by cutting a vertical slot that may extend to the surface. In the sublevel stoping method, a slot also may be opened across the center of the ore body. The holes that are fanned out from the sublevel drifts are blasted toward the slot, and mining proceeds as a systematic retreat in two directions away from the opening.

Processing

Mill flow lines are designed to suit the characteristics of a given ore body. Most raw fiber is recovered through a dry process that has

been used almost exclusively since the inception of chrysotile asbestos milling in Canada during the early 1900s.

Mill feed is derived from the underground or pit operation. Primary crushing may be done in underground stations, in the case of an underground mine; or in a surface plant, in the case of an open-pit mine. Although jaw or gyratory crushers are mainly used, some hand sorting may still be done in countries where labor costs are low. Hand sorting removes barren rock and recovers pieces of the larger veins used to produce No. 1 or No. 2 crudes.

Ore concentration is an important step in the milling of chrysotile and is particularly important for lower-grade ore bodies. It is not uncommon to discard as much as 40% of the mine ore through selective impacting and screening in the primary and secondary crushing circuits. Some producers use magnetic pulleys for upgrading the mine ore, although not all asbestos ore bodies are amenable to this type of separation.

The next step is to dry the ore. Most of the moisture is contained in the finer (–38 mm) fraction. At some plants, this fraction is screened and dried separately from the oversize (38 to 178 mm) material. Although the selection of a dryer is based largely on local preference, the two most commonly used are the rotary and vertical dryers. Fluidized-bed dryers also have been used. Generally, there is less mechanical damage to the fiber when vertical-tower and fluidized-bed dryers are used than with rotary kiln-type dryers. Rotary dryers, however, are preferable and are more effective for open-pit ores that might contain snow and ice. Oversize material can be separated before drying and bypassed to reduce the pebble-milling action of rotary dryers.

There should be adequate storage to protect the ore between drying and the main stage of milling. Besides assuring an adequate and more uniform supply of ore to the mill, further drying (up to 1% moisture loss) takes place during storage. The size of storage facilities varies with mill capacity.

Chrysotile fiber is released and separated from gangue by successive stages of crushing or comminuting by impact. Impactors are designed to release the fiber from the host rock and at the same time produce a minimum of fines. Fiber released by crushing is lifted by air suction, leaving most of the rock as a reject to go to the next stage of impacting and eventually to tailings. Finer fractions generally are screened out prior to air separation to avoid aspirating a large portion of host rock fines along with the fiber. Rotary aspirators designed to present a uniform layer of material to the aspirating hood are commonly used to improve the aspirating efficiency. The products of these first stages of separation may be considered as concentrates. They contain a large percentage of rock particles and must be further treated.

The concentrates are further graded and undergo a series of cleaning operations for the purpose of removing sand and dust. Screens, trommels, specific-gravity air separators, and modified forms of these, such as graders and dusters, further clean the fiber and separate it into standard-grade lengths.

In the grading mill, the fiber within each grade is further subdivided according to fiber quality. It is then subjected to several stages of screenings by means of shaking screens, gyratory screens, conventional trommels, trommel-like graders, and rotary dusters.

When well-opened or fluffed-out grades are required, the fiber is specially processed in one or more of a variety of machines. These range from graders or Willows mills (a fixed cylindrical casing with a rotating center shaft to which beater arms are attached) to one of several types of high-speed hammer mills, disk graders, or pulverizers. The type of machine or machines used depends on the length and type of fiber to be processed and the degree of opening or fluffing required. This additional treatment is generally given to

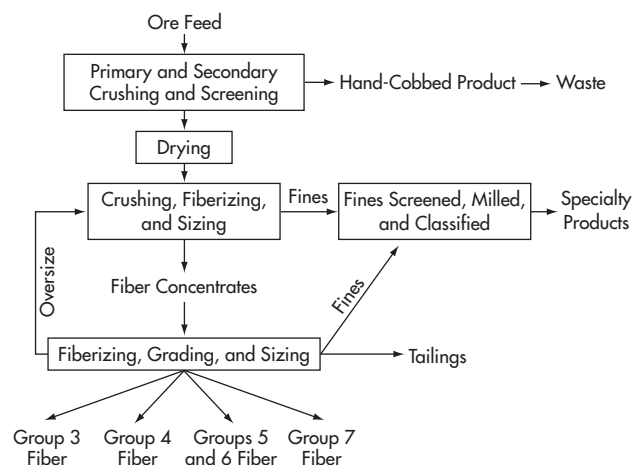

Figure 8. Generalized flow sheet of asbestos processing

the shorter fibers. A generalized flow sheet of the milling process is given in Figure 8.

A large volume of air is used in a chrysotile mill, most of which is for separating fiber from rock and dust by air suction and classification. An additional volume of air is required to reduce dust levels in the mill building to meet regulatory standards. Mills with a capacity of approximately 5,000 tpd of ore use 236 to >378 m³/sec of free air. The average consumption in Canadian mills is approximately 7 to 14 t of air per ton of ore treated (Rozovsky 1957; Kula and Wiser 1970). Modern practice requires that the air be filtered before being discharged from the mill into the open. Extensive bag filter units have been installed in all mills.

In Zimbabwe, South Africa, and Swaziland, beneficiation of chrysotile does not differ greatly from Canadian practice. One feature of African milling is the need to control moisture content carefully; particularly during the dry season it may be too low. Under extremely dry conditions, fibers may break or be damaged more easily.

MARKETING

Product Grades and Specifications

The most widely recognized test for classifying asbestos is the QS Test developed by QAMA, which has specifications for the various fiber grades based on the quantities of fiber that remain on each screen. Used for production control, the test determines the specification of the grade of fiber for sale. This test has been partially adopted by countries other than Canada, but in some cases the results are expressed in percentages instead of the ounces that Canada uses.

Wet classification and screening also have been used to monitor fiber lengths, nonfibrous fractions, and dust content during production. The McNett* or the Clark* wet-testing machine may be used for this purpose (Mining in Canada 1967).

A Ro-Tap* machine is sometimes used to evaluate further the QS sieve fractions. Many asbestos mill operators believe that the Ro-Tap gives a better distribution of the fiber lengths than the QS testing machine does.

Many customers use density measurements as a guide in producing specific products. In this case, the density of the asbestos

* Any use of trade, product, or firm names is for descriptive purposes only and does not imply endorsement by the publisher.

fiber is determined by filling a cubic-foot box or a fraction of a cubic-foot box with fiber. The box is then weighed, and the density is expressed as pounds per cubic foot (*Mining in Canada* 1967).

Many customers have developed their own tests for evaluating the performance of fiber in their finished products. The tests cover properties such as absorption, bulk, color, compressibility, flexing, grit, magnetite content, penetration, soluble salts, strength units, surface area, tensile strength, troweling, and viscosity (*Mining in Canada* 1967; Cossette and Delvaux 1979).

Fiber producers in other places, such as the Commonwealth of Independent States (CIS), South Africa, and Zimbabwe, developed their own testing methods for grading. Most fibers are sold according to the QST test because amosite and crocidolite are no longer mined.

Classification standards for grading chrysotile are given in Table 9. Amosite and crocidolite were generally not graded using the QAMA standard.

Uses

Asbestos Use by Group

Several thousand products were manufactured in the past that took advantage of the unique properties of asbestos. Some of the present and past uses for asbestos by grade and product type are discussed in this section (Badollet 1948; *Mining in Canada* 1967; Hodgson 1985; EPA 1988; Roskill Information Services Ltd. 1990; Harrison et al. 1999; Rice and Heineman 2003; also see U.S. Bureau of Mines and U.S. Geological Survey *Minerals Yearbook* chapters on asbestos for U.S. end use breakdown by fiber grade). Demand for crudes and Group 3 fiber has declined as manufacturing has shifted, in response to changing consumption patterns, to a greater use of shorter fiber. Groups 4 through 7 are the most commonly used fibers, with Group 7 fiber dominating. The crudes and groups are as follows:

- Crudes No. 1 and No. 2—Customers employ crudes to produce a long, spinning fiber for use in textiles. A desirable fiber for textiles is flexible, soft, low in soluble salts and magnetite, and easily carded without an excess drop in shorts. Fiber of this quality is desirable for all textile applications. Crude fiber has been used as felts in laminates, along with resins, to form a strong molded sheet for use in airplanes, boats, and so forth. By the late 1980s, demand for crude fibers began to diminish, and comparatively little crude asbestos currently is sold.
- Group 3 Milled Fibers—Chrysotile fibers that meet this classification may be used in textiles. Group 3 fiber also may be employed in asbestos papers, electrolytic diaphragms, gaskets, and insulating blocks. Some of the fibers of this group are used in laminates with resins. Like the No. 1 and No. 2 fibers, demand for Group 3 has declined as manufacturing needs have evolved.
- Group 4 Milled Fibers—Many grades of fibers in this group are used in asbestos-cement products such as boards, jackets, pipe, sheets, and a variety of hand-molded articles. Other applications are for brake linings, clutch facings, gaskets, millboards, papers, and plastics.
- Group 5 Milled Fibers—Products made with these fibers include asbestos-cement pipe and sheets, brake linings, corrugated or flat boards, electrical panels, gaskets, millboards, papers, and plastics.
- Group 6 Milled Fibers—Chrysotile fibers of this group are used in asbestos-cement corrugated and flat sheets, boards, brake linings, gaskets, millboards, papers, and plastics.

- Group 7 Milled Fibers—This grade of chrysotile is used in papers, cements, asphalt road pavement, asphalt roof coatings, brake linings, clutch facings, gaskets, millboard, paints, paper, plastics, and welding rods.
- Floats—Chrysotile floats may be used in coatings.

Asbestos Use by Product Type

The selection of asbestos fiber for a particular application depends on the processing method and the desired properties of the final product. Examples of major uses for asbestos fiber and factors that influence the choice of fiber grade and type are given in this section.

Asbestos-Cement Products

Pressure pipe that must conform to hydrostatic test specifications is produced outside of the United States from Groups 4, 5, and 6 fibers. In the past, chrysotile was blended with crocidolite to ensure a good modulus of rupture, but crocidolite is no longer used to manufacture asbestos-cement pipe. Flexural and impact strength requirements for asbestos-cement sheets usually can be met by using a Group 6 fiber. Formulations for corrugated sheets generally include some Group 5 material to improve adhesion of the wet sheets during the forming process. The asbestos content of pipe ranges from 15% to 25%; for sheet, 20% to 50%; and for shingle, 10% to 30% (EPA 1985, 1988).

In all asbestos-cement products made by the wet-machine process, drainage is an important fiber characteristic because it has direct bearing on the production rate. Preference is given to fast-filtering fibers. Amosite was once included in the formulation as a filter aid but is no longer used.

The strength or drainage requirements for shingles made by a dry process are not so exacting and can be satisfied with Group 6 or a blend of Groups 6 and 7. Other asbestos-cement building products may use fibers from Groups 4, 5, 6, and 7.

Asbestos Paper and Millboard

Asbestos fibers are used with an organic binder to manufacture a variety of millboard and paper products, such as electrical insulation, pipe coverings, and roofing felt. Various blends of Groups 3, 4, 5, and 6 fibers are used for this application, depending on the desired strength and porosity of the paper.

Felt for pipeline wrap applications is composed of 85% asbestos, with the remainder made up of cellulose fiber and binder. Millboard is a heavy cardboard-like material that can contain from 60% to 95% asbestos, although typical formulations use 70% to 80% asbestos. Commercial paper for insulation use, including corrugated paper, contains up to 98% asbestos. Rollboard, which consists of two layers of asbestos paper glued together with sodium silicate, generally is composed of 70% to 80% asbestos (EPA 1988). Average asbestos contents of roofing felts are about 85% but can approach 95% (Meylan et al. 1978; EPA 1988). Paper used in flooring felt as a backing for vinyl sheet floor products contains about 85% asbestos (EPA 1988).

Asphalt Products

Group 7 asbestos fiber, in combination with asphalt and various solvents, forms the basis of a wide variety of products such as caulking compounds and spray or brush-on roof coatings and also for asphalt road pavements. In asphalt products, asbestos contents range from 5% to 12% for bituminous coatings, 10% to 25% for roof putties, and 1% to 5% for liquid sealants (Meylan et al. 1978; EPA 1985, 1988).

Caulking and Sealing Compounds

Combinations of long fiber asbestos with cement and other ingredients, along with waterproofing resins, are used to produce special types of caulking compounds. Some caulks and sealants may use Group 3 fiber; others use short asbestos and floats (Groups 7, 8, and 9). These are combined with various types of resins and other materials to produce a soft plastic caulking compound, which can be controlled either to remain soft or to set up as a hard mass.

In caulking and sealing compounds, asbestos contents range from 1% to 5% for adhesives and cement; 5% to 25% for caulking, glazing, and patching compounds; 2% to 15% for paints; 2% to 10% for plasters; and 3% to 5% for spackles (Meylan et al. 1978; EPA 1985, 1988).

Friction Materials

A wide variety of products are classified under the friction materials category. Products are made with fibers ranging from Group 3 spinning grades to the shorter Group 7, with shorter Groups 5, 6, and 7 dominating.

Brake linings and pads contain 30% to 70% asbestos depending on the application (Rosato 1959; Meylan et al. 1978; Hodgson 1985). Drum brake linings contain as much as 60% asbestos, and disk brake pads from 25% to 30% (Meylan et al. 1978; Pye 1989; Harrison et al. 1999). Brake formulations also are different for cars and trucks. The composition of brake lining compositions in cars averaged 55% asbestos in 1968; that of trucks was 33% asbestos (Meylan et al. 1978).

Some clutch plates are made using asbestos open-weave cloth impregnated with resin and bonded to a steel disk. Most are manufactured by molding a dry resin-fiber blend under conditions of high temperature and pressure onto a packing plate. For the first method, a Group 3 fiber is required, whereas the molding process uses a Group 5, 6, or 7 fiber.

Most automobile brake linings bonded to a steel shoe are made from Group 7 fiber in a semiwet extrusion process, whereas heavy blocks for railcars and large vehicles use Groups 5 or 6 fibers, dry-molded and machined to finished dimensions. Groups 6 and 7 are used in disk brake-pad formulations.

Gaskets

Latex asbestos paper made from Group 7 fiber can be densified and used for gasketing, but most sheet-packing material is formed on a sheet machine by a calendering process. This latter method requires a longer fiber in the Groups 3, 4, or 5 categories that have been cleaned and opened. The fiber is blended with natural or synthetic rubber, plasticizers, and other ingredients in a high-shear mixer to form dough that is later calendered into sheets of various thicknesses. Fibers from Groups 6 and 7 may also be used to manufacture gaskets.

Packings can be made with loose fiber, formed of asbestos and binders, woven into braided asbestos products, and made using asbestos yarns. Asbestos content varies depending on the use, with higher fiber levels associated with higher-temperature applications (EPA 1988). In some packing products, asbestos content is generally more than 75% and often as high as 100% (Meylan et al. 1978).

Plastics

Asbestos, or a combination of asbestos and glass fiber, is used to reinforce some structural plastics. The asbestos may be in the form of a mat, or as paper or cloth, to form laminates with resins such as polyesters, phenolics, thermosetting silicones, melamines, and furanes. Short Group 7 fiber and floats also are used as fibrous filler

for the production of molded phenolic resin and polyester parts. In such applications, freedom from abrasive particles is especially important to hold die wear at a minimum level. Fibers of Groups 3, 4, 5, and 6 also may be used to reinforce plastics.

The average asbestos content of plastic in the mid-1980s was 17% (EPA 1985). Phenolic compounds contained 50% to 60% asbestos, and other resins may have required as little as 5% asbestos (Meylan et al. 1978). Asbestos contents of vinyl flooring ranged from 8% to 30% (Rosato 1959; Meylan et al. 1978; EPA 1980, 1985, 1988).

Textiles

Long spinning grades of chrysotile are used to manufacture textiles for various applications. Fibers of Groups 1, 2, and 3 are used for this process.

Consumption

Current Consumption

The actual worldwide consumption of asbestos, in weight, has been poorly documented in terms of end-use breakdown and even total consumption.

In 2002, brake linings and pads, gaskets, and asphalt roof coatings comprised the bulk of U.S. consumption. Of that, asphalt roofing compounds accounted for about 80% of U.S. consumption, gaskets for 8%, friction products for 4%, electrical and thermal insulation for 4%, and miscellaneous uses for 4%. This is a considerable change from 1978 when asbestos-cement pipe and sheet and flooring were the major U.S. markets. Table 10 presents a timetable of asbestos consumption in the United States from 1965 to 2002.

In 2000, world consumption of asbestos fiber was about 1.83 Mt. The largest consuming region was Asia and the Middle East, with an estimated 861,000 t, followed by Europe with 691,000 t, South America with 207,000 t, Central and North America with 35,000 t, Africa with 30,500 t, and Oceania (consisting of Australia and New Zealand) with 1,250 t. Most of the asbestos was used to manufacture asbestos-cement products. The largest users of asbestos were, in descending order by tonnage, Russia, China, Brazil, India, Thailand, Japan, Ukraine, Indonesia, Uzbekistan, and the Republic of Korea (Table 11). All other countries appear to have consumed less than 20,000 t each since 1998 (Virta 2003).

Historical Consumption

Based on qualitative descriptions, asbestos-cement products are thought to have dominated the asbestos-manufacturing industries since the early 1900s. A description of the 1930s asbestos industries in manufacturing countries implied that asbestos-cement corrugated and flat sheet, pipe, and roofing tile were the major markets for asbestos (Bowles 1955). The low cost of asbestos-cement products, their durability and effectiveness, and the unsophisticated technology required to make these products would have been major factors leading to their widespread use, particularly for developing countries with limited mineral and monetary resources (Bowles 1955). Rosato (1959) indicated that, in the later 1950s, asbestos-cement products for commercial and industrial buildings and private homes consumed the largest quantity of asbestos. No estimate was made, however, on percentage of consumption. In 1980, asbestos-cement products reportedly accounted for about 66% of world consumption of asbestos. In regions where alternative construction materials were available, the demand for asbestos-cement products was proportionally smaller, and a much wider variety of other asbestos products were developed. Asbestos-cement products accounted for only 45% and 43% of the U.S. and Western European markets, respectively (Table 12).

† Estimated data.

‡ na = Not available.

With the onset of the asbestos health issue in the 1970s, demand for asbestos products declined in the United States and Western Europe, where noncement applications dominated. Consequently, the percentage of asbestos-cement products in the asbestos world market increased, rising to 80% in Africa; 76% in Asia, Eastern European countries, and South America; and 60% in Oceania in

1980 (Roskill Information Services Ltd. 1983). With the continued decline in the use of asbestos in the 1980s and 1990s, markets have shifted even more toward asbestos-cement products. In 2002, asbestos-cement products are thought to account for more than 98% of the world's consumption of asbestos (Virta 2002). Other markets for asbestos are paper, textiles (comprising yarn, thread, cloth, tape,

or rope), the rmal and electrical insulation, g askets, and friction products, including brake or clutch pads. Some specialty plastic products are still manufactured.

Historical Trends in Consumption, by Region

North America. For much of the 20th century, the United States was the largest user of asbestos. The expanding population, the abundance of available capital for investment in the relatively new asbestos industry, and the large demand for construction of housing, public buildings, and roads were major contributing factors. Within a couple of decades of having begun its asbestos industry, the United States became a world leader in usage and held that position through the 1960s. During that time, the United States accounted for 30% to 83% of world apparent consumption. In the 1960s, the United States was replaced by the former Soviet Union as the leading user of asbestos. After that time, use of asbestos in the United States declined rapidly in response to asbestos-related health issues.

In Central America, Costa Rica, Cuba, the Dominican Republic, El Salvador, Guatemala, Honduras, Jamaica, Nicaragua, and Panama have been small consumers since the 1960s, using only a few thousand tons annually. Canada's exports of asbestos overshadowed its relatively small asbestos-manufacturing industry. From 1940 to 1970, consumption in Canada probably was around 45,000 t annually and currently is estimated to be less than 10,000 t annually. Consumption in Mexico gradually built up to 79,000 t in 1980 and then declined to an estimated 27,000 t in 2000. In that same year, Cuba, the Dominican Republic, El Salvador, and Panama were the only other North American countries believed to be using asbestos.

Europe. After the United States, Europe was the next region to develop a significant asbestos-manufacturing industry. Through the first half of the 20th century, the United Kingdom became the major European consumer, followed by many other European countries. By 1930, Belgium, Germany, Luxembourg, and the United Kingdom were major suppliers of asbestos products throughout Europe and Asia. Demand in the former Soviet Union exceeded

that of the United Kingdom by 1950 and that of the United States by 1970.

Between 1950 and 1960 the asbestos industry in Europe experienced its greatest expansion up to that time, increasing to 1.17 Mt from 507,000 t in 1950. Consumption increased significantly in Austria, Belgium-Luxembourg, Czechoslovakia, Denmark, France, West Germany, Italy, the Netherlands, Poland, the former Soviet Union, Spain, Sweden, Switzerland, the United Kingdom, and the former Yugoslavia. A significant portion of the growth during the 1950s can be attributed to the continuing reconstruction efforts in Europe following World War II.

The asbestos health issue, which affected U.S. markets by the mid-1970s, also began to affect asbestos use in Europe. After 1980, demand in all large consuming European countries, except the former Soviet Union, began to decline. In the 1990s, production in Kazakhstan and Russia declined significantly, and many European countries, and eventually the European Union, voted to ban the use of asbestos. Consumption was estimated to be 691,000 t in Europe in 2000, mostly in the former Soviet Union.

Asia. Growth in the Asian (including Middle Eastern countries) markets lagged behind that of Europe and the United States. Cultural and governmental differences guiding infrastructure and technological development, and fiscal restraints all contributed to the slow growth in the asbestos segment. It was not until the 1950s that significant manufacturing industries developed, increasing consumption to an estimated 667,000 t in 1970 from 25,400 t in 1950. In the early stages of the industry, China and Japan accounted for the largest increases. The 1980s brought about a shift in manufacturing in Asia with increased production in India, Indonesia, Iran, the Republic of Korea, and Thailand. In 2000, China accounted for 48% of the apparent asbestos consumption in Asia, mainly to satisfy its own domestic demands. India was the next largest consumer, with 15% of the market, followed by Thailand with 14%, Japan with 12%, India with 8%, Indonesia with 7%, and the Republic of Korea with 4%.

Africa. Consumption in Africa has been rather low throughout most of the 20th century, peaking in the 1990s. Slow population growth, limitations on land amenable to development, slow dissemination of new technologies, governmental policies toward development, and fiscal restraints influenced the progress of the asbestos industry in Africa. Significant consumption did not occur until the 1970s when 90,300 t were used. Although erratic in its consumption, Nigeria, with the largest African population, was the largest user of asbestos. After the 1970s, consumption in most countries in Africa began to decline. Consumption in Africa was estimated to be about 30,500 t in 2000, distributed among several countries.

South America. The asbestos industry in South America was very small until the 1960s when Brazil began producing asbestos. By 1970, Argentina, Brazil, Colombia, and Venezuela had the most active asbestos-manufacturing industries in South America. By the mid-1970s, Brazilian production expanded, and Brazil soon became the dominant South American producer and consumer of asbestos. With the onset of the asbestos health issue, consumption in most South American countries declined. Consumption in South America was estimated to be 207,000 t in 2000, with Brazil accounting for about 88% of consumption.

Oceania. Both Australia and New Zealand produced and consumed asbestos in the early part of the 20th century. Consumption peaked in 1975 with Australia accounting for most of the volume. With the asbestos health issue of the 1970s, production and consumption declined to 1,250 t in 2000 (Virta 2002).

In looking at the 20th century as a whole, total asbestos production was estimated to be around 174 Mt between 1900 and

Table 13. Changes in apparent consumption, by decade, t

2000. Assuming some loss during processing, the total amount of asbestos consumed for manufacturing during the 20th century would be in the range of 140 Mt to 160 Mt. Decadal changes by region, and countries that account for the bulk of the shift in asbestos consumption between 1920 and 2000, are given in Table 13.

Prices

Table 14 gives the latest published prices for chrysotile from Canada and South Africa.

Asbestos Substitutes

In response to environmental and liability issues, the use of asbestos substitutes and alternative products has increased. Product manufacturers have been replacing asbestos with different materials, redesigning old products to eliminate the need for asbestos, or designing new products that require neither asbestos nor asbestos substitutes. Some of the factors considered in making the switch include the cost of the substitute, cost of the additional manufacturing, and the cost of the product design, plus product performance. Possible health

risks, many of which are unknown over the long term, also have to be considered when using substitutes (Hodgson 1985; EPA 1988).

Examples of materials substituted for asbestos include aramid fiber, cellulose fibers, ceramic fiber, fibrous glass, graphite flake and fiber, mica, polyethylene fiber, polypropylene fiber, polytetrafluoroethylene fiber, steel fibers, and wollastonite. Examples of alternative products include aluminum, vinyl, and wood siding; aluminum pipe and sheet; asphalt coatings; ductile-iron pipe; fiberglass sheet; polyvinyl-chloride pipe; prestressed concrete and reinforced concrete pipe; semimetallic brakes; urethane coatings; and vinyl composition floors (Hodgson 1985; EPA 1988; Harrison et al. 1999; Roskill Information Services Ltd. 1990; also refer to the Asbestos Substitutes chapter in this book). No single substitute has proved to be as versatile as asbestos.

REGULATORY AND ENVIRONMENTAL CONSIDERATIONS

Health and Safety

Asbestos-related disease is one of the most widely studied subjects of modern epidemiology (WHO 1986; Bignon, Peto, and Saracci 1989). It includes asbestosis (a lung fibrosis resulting from long-term, high-level exposures to airborne fibers), lung cancer (usually resulting from long-term high-level exposures and often correlated with asbestosis), and mesothelioma (a rare form of cancer of the lining [mesothelium] of the thoracic and abdominal cavities) (Omenn et al. 1986).

Concerns over its health effects were first raised in the early 1900s in the United Kingdom, but it was not until the early 1960s that researchers established a positive correlation between worker exposure to asbestos fibers and respiratory cancer diseases (Selikoff, Churg, and Hammond 1964; Murray 1990). This triggered a significant research effort to unravel important issues such as the influence of fiber size, shape, durability or persistence in the lungs, trace elements, and exposure levels and duration with health effects (van Oss et al. 1999; Churg and Wright 1994; ATSDR 2001; Rice and Heineman 2003). It is generally agreed that the inhalation of long (generally greater than or equal to 5 μm), thin, and durable fibers in high concentrations over a long period of time pose the greatest health risk. Shorter fibers penetrate deeper into the lung, but longer fibers are more difficult to clear (Timbrell 1982; Finkelstein and Dufresne 1999).

Fiber solubility is suggested to be the second most critical factor. Chrysotile is more soluble than amphibole asbestos and is more rapidly removed, reducing its residence time in the lung. Duration of exposure to asbestos is important because long exposure periods increase lung burden, with long and/or high exposure levels counteracting the effects of fiber solubility. Different asbestos types also appear to activate phagocytic leukocytes differently, with crocidolite and some chrysotile samples being the most active (van Oss et al. 1999). Research suggests that iron content may be important in asbestos-induced toxicity (ATSDR 2001).

Although the subject is still debated, many health scientists believe that there is sufficient evidence to state that the genotoxic and carcinogenic potentials of all asbestos-fiber types are not identical; in particular mesothelial cancer is most strongly associated with amphibole fibers (Gardner and Powell 1986; Dement 2001; Gibbs 2001; Nolan et al. 2001; Wilson and Price 2001; Bernstein, Chevalier, and Smith 2003; Bernstein, Rogers, and Smith 2003).

The issue of asbestos as a contaminant in ore bodies also is a concern (Nolan, Langer, and Wilson 1999; Hull, Abraham, and Case 2002; Peipins et al. 2003). As a means of defining the types that may contain asbestos as a contaminant, two studies were recently conducted on talc and vermiculite deposits. In the study of

U.S. talc deposits, it was determined that talc formed through hydrothermal processes consistently lacks amphiboles as accessory minerals. Talc bodies formed through contact or regional metamorphism, however, consistently contained amphiboles, locally as asbestiform varieties (Van Gosen et al. 2004). In U.S. vermiculite deposits, preliminary studies suggest that fibrous amphiboles are most likely to be associated with zoned, alkalic/calcic, quartz-poor plutons, such as the vermiculite deposit near Libby, Montana (Van Gosen et al. 2002).

Regulation

Environmental and liability issues continue to affect the asbestos industry. As the concern over the health risks posed by low-level exposures to asbestos increased, the United States and other countries have enacted stricter exposure regulations. More emphasis is being placed on environmental exposures than in the past.

Some countries have opted for a broader approach and have adopted regulations that also minimize exposure of the general public to environmental asbestos fibers by banning or restricting asbestos imports and types of applications. Countries that have banned (either a complete ban or a ban with exemptions) or are phasing out the use of asbestos, and in some cases asbestos products, by 2005, include Argentina, Austria, Belgium, Chile, Denmark, Finland, France, Germany, Italy, the Netherlands, Norway, Poland, Saudi Arabia, Sweden, Switzerland, and the United Kingdom (Virta 2002; International Ban Asbestos Secretariat 2004). In 2005, the European Union banned asbestos use by its members in most applications.

OUTLOOK AND FUTURE TRENDS

Legal actions and adverse publicity on asbestos have taken their toll on asbestos markets, despite much stricter asbestos regulations. World consumption declined from an estimated 4.84 Mt in 1980 to about 1.83 Mt in 2000. Although a few countries have increased or maintained their production through 2002, consumption has declined significantly in most countries. This trend is expected to continue because of increased pressure to reduce or ban asbestos usage in major consuming countries.

Despite the current bans and continued opposition to the use of asbestos, markets for asbestos probably will continue to exist into the future. Consumption can be expected to decline as substitutes and alternative products gain favor in remaining world markets and as additional countries enact bans on the use of asbestos. This process will occur over many years, and even then, there probably will remain specialized applications for asbestos, particularly for matrix-based products.

ACKNOWLEDGMENTS

Many thanks to Nora K. Foley, geologist, U.S. Geological Survey; Bob Pigge, president, Asbestos Information Association/Northern America; and Pierre Laroche, engineer, LAB Chrysotile, Inc., for their technical reviews of this chapter. Thanks also are expressed to Robyn Sandler for her assistance with editing and manuscript preparation.

Barium Minerals

Paul Mills

INTRODUCTION

The word *barium* comes from the Greek word *barus*, which means heavy. The common barium minerals are *barite* and *witherite*. Barite is by far the predominant barium mineral used by industry. Barite is also known as *barytes*, and in the area around Potosi, Missouri, it is called *tiff*. Barite has been found in many areas around the world, and the mineral is mined and processed in numerous countries. Because the mineral has a high density and is chemically inert, it is ideal for use in the petroleum, automotive, and paint industries, and in other applications. The purpose of this chapter is to help one identify barite, locate the mineral, and understand its uses and the way the mineral is currently being mined. The reader is also referred to the Barium Minerals chapter in *Industrial Minerals and Rocks*, 6th edition (Brobst 1994).

PRODUCTION, RESOURCES, AND RESERVES

The four top barite-producing countries in the world are China, India, Morocco, and the United States, according to the information compiled and reported by the U. S. Geological Survey (USGS). Table 1 is based on information supplied by the USGS (Searls 2004), which outlines the reserves and production for 2002 and estimated values for 2003. Values are given in thousand metric tons.

The reserve base is the in-place demonstrated (measured plus indicated) resource from which reserves are estimated. The reserve base includes those resources that are currently economic and marginally economic, along with some that are not currently economic.

Not all the barite reserves have been identified. There are still possible locations for new or additional barite reserves.

GEOLOGY

Mineralogy

Chemically, barite is barium sulfate with the formula of BaSO_4 . It can be identified by its high specific gravity, which is 4.50 g/cm^3 when in pure form. The mineral has a hardness of 3.0 to 3.5 on the Mohs hardness scale and belongs to the orthorhombic crystal system. It can also be identified by its white streaks and vitreous to pearly luster. The cleavage of the mineral is perfect on {001} but imperfect on {010}. It normally has thick to thin tabular crystals, an example of which is the *desert rose*, a cluster of reddish barite crystals. Barite comes in a variety of colors, including yellow, white, brown, gray, and blue; it can also be colorless.

Table 1. World mine production, reserves, and reserve base, kt

	Mine Production		Reserves 2002	Reserve Base 2002
	2002	2003*		
Algeria	45	50	9,000	15,000
Brazil	55	55	2,100	5,000
China	3,100	3,500	62,000	360,000
France	75	75	2,000	2,500
Germany	120	125	1,000	1,500
India	600	900	53,000	80,000

United Kingdom	60	60	100	600
United States	420	480	26,000	60,000
Other Countries	420	290	12,000	160,000
Total (rounded)	6,000	6,700	200,000	740,000

* Estimated.

† na = not available.

The mineralogical name for the carbonate barium mineral is witherite, which has a chemical formula of BaCO_3 . Unlike barite, witherite is not chemically inert. Witherite can dissolve in water and, when dissolved, can cause an environmental hazard.

Origin and Mode of Occurrence

Barite forms in many geologic environments and can be found with both metallic and nonmetallic minerals. The barite can either be the major component of the material or only a minor fraction. In most cases, the barite must be a major component of the material and must be of substantial thickness for the ore to be economic. There are three main types of deposits: vein, residual, and bedded.

Vein, Filling, and Replacement Deposits

The vein deposits are epigenetic deposits of hydrothermal origin with the barite precipitated from solution and filling or replacing

rocks along fractures or other structures. The barite was often deposited in fault fractures or along bedding planes. Because of the nature of the deposit, the barite-mineralized zone can vary greatly in length and width. It is not uncommon for the main mineralized zone to pinch and swell along the fracture structure, and the zones tend to pinch out on each end. The deposit can have fractures filled with barite radiating from and perpendicular to the main barite zone. The barite is normally white, but sometimes is stained by secondary iron oxides. The common impurity is quartz, but at times the ore is associated with metallic minerals such as pyrite and marcasite. Some veins contain only quartz and perhaps calcite as impurities. Many of the vein deposits with low amounts of impurities have been used by the paint industry.

Residual Deposits

The residual deposits are of hydrothermal origin. The host rock, which in most cases had been limestone or dolomite, has been removed by extensive weathering. The barite, which filled fractures in the host rock, is now contained in unconsolidated material such as clay. The depth to which the barite has been liberated depends on the depth of the weathered zone, which can be as deep as 100 m. Generally the barite content in the unconsolidated material is low. Because it is easier to mine unconsolidated material than rock material, and it is less difficult to separate the barite from unconsolidated material, a residual deposit can still be economical even though the barite content is low. The barite in a residual deposit is white in color. The major impurity associated with the barite is quartz, but pyrite, marcasite, galena, and fluorite can also be present.

Bedded Deposits

The bedded barite deposits are stratiform deposits that are part of a sedimentary sequence. This type of deposit typically is found with units of chert, mudstone, and siltstone. The origin of the bedded barite deposits in Nevada and elsewhere has been a controversial subject. Early workers suggested that the deposits in Nevada were formed by hydrothermal replacement of limestone or chert (Gianella 1940; Ketner 1963). Dunham and Hanor (1967) first suggested that the deposits were penconemporaneous with the enclosed sediments and that the barium was derived from hydrothermal fluids. Numerous studies in the late 1960s to early 1980s added much new data and generally supported the sedimentary-hydrothermal characterization of the deposits. Much of these data were summarized by Papke (1984) and Harben and Bates (1990). It has now been fairly well established that the bedded barite deposits are of submarine-exhalative origin. Barium in fluids moved upward along fissures in the ocean floor and discharged from submarine hot springs, where it combined with sea water sulfate to form barite. This process explains the many sedimentary features as well as the local replacement and alteration of adjacent rocks. Biological activity was no doubt important, especially in producing the sulfide ions that reacted with metal or hydrogen ions, but a source of introduced barium in solution was needed to form the typical bedded deposit of nearly pure, thick barite. Many details about the exact environment of deposition are still being debated, and the origin of the deposits has not been resolved to everyone's satisfaction.

Bedded barite varies in thickness and length. The thickness, length, and purity of the deposit will vary with the relationship of the sedimentary process and submarine hot springs at the time of deposition. The length of the deposit can be more than 300 m and the thickness more than 30 m. The deposit can also be short in length and narrow in thickness. Bedded barite is generally light to dark gray. The barite is normally interbedded with chert or argilla-

ceous material. The major impurity is quartz. Bedded barite contains several percent of organic carbon and is commonly rich in hydrogen sulfide. Brachiopods and other fossils are sometimes present as a mold or replaced by barite.

MAJOR DEPOSITS

United States

Arkansas

The large bedded deposit near Magnet Cove, Arkansas, is a bedded deposit that is folded into a plunging syncline. The barite is gray to blue-gray in color with some interbedded black shale. The barite is tightly bound with quartz and black shale. The mining in this area started in the 1940s, first by the open-pit method and later by underground mining. The deposit was last mined in the late 1970s. Flotation was required to process the ore. The material was used by the petroleum industry.

Georgia

The Cartersville Area contains several barite deposits, which are considered to be hydrothermal in origin, filling fault and fracture zones (Kesler 1940). These are residual deposits because the host rock has been eroded away, leaving the barite ore in the resulting clay beds. Some of the ore is tightly bound with quartz, which means that the ore must be crushed to about 70 mesh for the barite to be separated from the waste material. Flotation or a combination of jigs and flotation have been used to recover the ore. The barite is white in color, but because some iron oxide is present with the processed ore, it has a light brown color. Mechanized mining started in the early 1900s, and continues today. The barite from this area is generally used in the industrial grade market.

Missouri

The Potosi Area has several barite deposits, which are residual deposits. The barite is believed to be hydrothermal filling of fault fractures. The host rock weathered away, leaving the ore in reddish clay. The barite ore is white. The associated minerals are drusey quartz, agate, weathered marcasite, some galena, and goethite. The ore is not tightly bound with any of the associated minerals; therefore, a washing plant has been used to recover the barite. The processed ore was light to dark brown because of the presence of the iron oxide. Hand-mining started in this area in the 1800s, and mechanized mining started in the late 1920s. The last mine in this area was closed in the 1990s. The material has been used by the petroleum, paint, and medical industries after further processing.

Nevada

There are several active barite mines in the Battle Mountain area. The barite deposits in this area are bedded barite deposits. The ore is light to dark gray and is associated with argillaceous rocks and chert. Some of the deposits in this area are pure enough to be mined and shipped without any additional processing. The remainder of the ore requires jigs or a combination of jigs and flotation to separate the barite from the waste material. There are also numerous vein and bedded deposits in Nevada. Some of the mining operations in Nevada began in the 1940s. The open-pit mining method is currently used in Nevada. The ore is used in the petroleum industry.

Tennessee

The Sweetwater area has several residual barite deposits. The barite is associated with fluorspar and some iron oxide. A washing plant containing barrel screens, dewatering screws, and jigs was used to recover the ore. The barite deposits in this area were mined until the 1990s. The ore was used mainly by the petroleum industry.

Other Countries

Brazil

There is an active mine in the Camamu Area. The barite is a vein deposit and some goethite and limonite are associated with the ore. The open-pit method is used to mine the ore. The ore is obtained using selective mining and washing/screening to separate the waste product.

Canada

There are several unmined bedded deposits in the Yukon Territory, and there are deposits in Nova Scotia and Newfoundland. The method used to process the ore in Nova Scotia varies with the deposit. One deposit requires flotation, and another requires tables and/or jigs to process the ore. The Newfoundland deposit requires flotation to process the ore.

China

There are several barite deposits in China. A large bedded deposit in the Hunan Province is folded into a plunging syncline. The deposit has a very long strike but is only a few meters in thickness. The ore is mined by the open-pit method, and in some areas, short drifts and shafts are used to retrieve the ore. The ore is mined by hand, the grade is controlled by hand picking and selection.

An ore deposit in Guangxi Province is of vein origin. The ore is white, with some iron oxide associated with the barite. The ore is mined by the open-pit method, and in the area of Yong Fu, the ore is retrieved using the underground mining method. The ore is mined and selected by hand. There are also several residual deposits located in the Guangxi Province.

A deposit of barite in Guizhou Province also is of vein origin. The ore is bright white and can be used by the paint industry. The ore is hand-mined and selected.

India

The major barite mine in India is a bedded deposit. The ore, which is dark gray, has been folded into a plunging syncline. The estimated reserves of the deposit are approximately 70 Mt.

Mexico

There are several bedded deposits in the Hermosillo Area. The deposits are very similar to those in Nevada. Some of these deposits were reported by Poole, Madrid, and Oliva-Becerril (1991). The ore is light to dark gray in color. The ore was separated from the siliceous waste by jigs. There are some deposits that require a combination of jigs and flotation. Other deposits in Mexico are located in the Pueblo, Monterrey, and Durango areas. Open-pit mining has been used to retrieve the ore.

Other Deposits

There are also barite deposits in Morocco, Ireland, France, Germany, Italy, Iran, North Korea, Thailand, Turkey, Algeria, Russia, and several other countries.

TECHNOLOGY

Exploration Techniques

Many barite deposits are located by the discovery of an outcrop or float material found in streams, drainages, and road cuts. After the initial discovery, additional work is done to determine the extent of the deposit. This is normally done through mapping the outcrop or location of the float material. When the outcrop is located, a series of trenches are normally dug perpendicular to its strike to determine the length and size of the deposit. Ore samples are collected from

the trenches to determine the quality, composition of the ore, and rough economics of the deposit. The first tests performed will indicate if the material can be marketed and can also indicate the cost involved to bring the ore to market.

The discovery of the first outcrop or deposit can assist in locating other similar ones. The barite deposit may be displaced into additional segments as a result of faulting. The mapping of the fault structures in the area might lead to locating extensions of the barite deposit. Also, depositional information might assist in locating other deposits. In Arkansas, the barite deposits that have been mined are located at the boundary between the Arkansas Novaculite and the Stanley Shale. The deposit located near Magnet Cove, Arkansas, is about 96 km from the deposits in the Fancy Hill District, but all the deposits are in the same geologic sequence.

After the deposit has been located, and it has been determined that the deposit warrants additional investigation, drilling is used to determine the depth and quality of the ore in vein and bedded deposits. Normally, reverse-circulation, air-hammer drills are generally used for drilling up to several hundred meters in depth. The drill cuttings are collected at intervals, keeping the ore zone samples separate from the overburden samples. The drill cuttings can be used in a series of tests that determine the economics of the deposit. Specific gravity normally is run on every sample collected of the ore zone. On a composite of the ore zone samples, the amount of mercury, cadmium, and water-soluble alkaline earth metals is sometimes tested. The drilling sample can also be used in tests to determine the best method to upgrade the ore. Tests such as liberation size, sink float test, and plant pilot test can be used to determine recovery method and estimated cost for recovery. It should be noted that because of the nature of the reverse-circulation drilling method, some samples can be contaminated with upper formation material.

If higher accuracy or additional information is required, core drilling is then used. Core drilling is also used to reach to greater depths. Core drilling is more expensive than air-hammer drilling, but it can eliminate contamination and allow additional information to be gathered. With the core retrieved, the angle of the ore zone can be measured and any fault zones can be located. In some cases, the direction of movement along fault planes can also be determined. In addition, the relationship between the ore and waste zones can be more clearly defined. Specific gravity and mercury, cadmium, and water-soluble alkaline earth metals contents can be determined from the core samples to estimate the quality and marketability of the ore. Metallurgical testing can be done to determine the recovery method required to market the ore.

When evaluating a residual deposit, auger drilling or trenching using a large backhoe or excavator is used to determine depth, quality, and quantity of the barite. When the ore zone is shallow, the trench method can then be used to collect samples and map the ore zone. When the barite zone is deeper than 6 m or below the reach of the backhoe bucket, drilling is required. The samples collected are tested for the percentage of barite. The mixed clay and barite can be used to determine the recovery method. In most cases, the clay is removed, and liberation and pilot tests are performed on the remaining rock material to determine the method of recovery and economics of the ore.

When evaluating an ore deposit to determine if the ore will be economic, special care needs to be taken to analyze the possible effects of associated minerals. If the mining operation exposes unoxidized minerals such as pyrite, these minerals will possibly react with rainwater and cause an acid water discharge. The state of Nevada now requires that a potential acid generating test be performed on the ore and mining/upgrade process.

Figure 1. The Rossi mine

From the information gathered about a deposit, a mine plan can be developed. Most barite mining operations today use the open-pit method to extract the ore. This type of mining is ideal for near-surface deposits with various angles of dip. Barite has on rare occasions been mined using underground methods. Underground operations are normally used for deeper deposits. Also, this method is sometimes used at the later stages of mining where the open-pit method was used in the beginning phase. The barite operation at Magnet Cove, Arkansas, is a good example of this type of mining. The underground method can also be used when property rights or other factors restrict the extent of the surface disturbance. In all cases, the ore body must be evaluated to determine which method is the best from an economic and safety standpoint. Figure 1 is a photo of the Rossi Mine, an open-pit barite mine located in Nevada.

Much care must be taken to remove the mined barite with as little waste contamination as possible to reduce processing costs. In some cases, it is very difficult to eliminate the waste because of the nature and type of deposit. In a residual deposit, a high percentage of the material is waste, and current mining equipment is not capable of separating the clay waste. Therefore, the ore-bearing waste is mined and hauled to the processing plant for separation. A bedded barite that has thinly bedded shale, chert, or a gillite also is mined and hauled directly to the processing plant with very little waste separation. If the bedded or vein barite zone is pure enough and of sufficient size, the ore zone may then be mined to produce barite that will meet specifications without further processing. In many cases, the waste on the hanging wall of the ore must be removed first. Removal allows the mining equipment to mine the ore cleaner and with less waste contamination. When the dip of the barite is nearly vertical, the barite sometimes can be mined leaving the waste on both sides of the ore. In some of the hand-mining operations in China, the ore is removed and the waste is left in place.

Barite Processing

Several processes have been developed and used to separate the waste material from the barite. Each method has its own unique requirements and limitations. The processes that can be used are hand selection, screens, washing, jigs, tables, spirals, and flotation. One or a combination of several different methods may be required to separate the waste from the barite.

Hand Selection

Hand mining, or selection by hand, can be done in areas where the cost of labor is low and/or where hand selection will achieve the desired quality of barite. In some areas of the world, the cost of labor is low enough that the barite deposit can be mined and the barite separated from the waste by manual labor or hand selection. The laborers must be able to easily identify the ore and determine quality. To aid in the separation, the waste and ore should have different colors or other physical differences that are easily discernible by eye. A deposit of high-purity white barite flanked by brown sandstone would be easy to separate by hand. Separation by hand is used by the Chinese to produce the high brightness barite used in the U.S. paint industry. The barite that is iron stained or contains minerals that will cause the brightness and whiteness to drop is removed by manual labor. There are optical sorters that can remove off-white product, but nothing is better than the human eye and hand.

Screening

Screening or the combination of crushing and screening can remove some clays, fine-grained waste, or other waste with different breaking characteristics than barite. Screens are ideal for removing some clay and subsoil, with the barite produced as oversize and the waste as fines. This removes the lower specific gravity material and raises the specific gravity of the final barite product. In some cases, screening has been used to raise the specific gravity of ore from a deposit that consists of shale and barite. Because the shale breaks in a different manner than the barite, some of the shale can be removed by screening. Some screening is currently being done in Nevada.

Washing

Washing the ore with a dewatering screw, barrel screen, or logs removes special types of clays and subsoils where material is hard to break up. A washing-type system is used mainly with residual type deposits, but can be used on other deposits as well. The object of this method is to remove large amounts of clay from the rock material. The material can be either ore-bearing material that will be sent to an additional process to complete the separation or material that will meet specifications without any additional work. In one area in China, dewatering screws are used to wash away the clay material and the resulting material is drilling-grade barite. The barite processing plants in Georgia, Tennessee, Missouri, and Brazil all use or used washing in the first stages of operation.

Jigs

Jigs are used all over the world to separate barite from other rocks and minerals. Jigs use pulsating water to separate barite from the waste by gravity. The feed must be crushed finer than a predetermined liberation size, namely the size to which the ore must be crushed to liberate the barite from the waste. The feed size also must be the size that the jig can handle.

Several different brands of jigs and several different jig configurations are available. Some jigs are capable of handling crushed material the size of a large sand grain. Most jigs operating today handle crushed material that is 12.5 mm in diameter or less. The way the jig works is that crushed feed is constantly being added on top of a screen. Water is added in the lower part of the jig below the screen, filling the jig several centimeters above the screen. Excess water runs off the end of the screen, carrying with it some of the waste material. The jig has a plunger or other method to pulsate the water. The pulsating water lifts the feed material, allowing the heavy barite

to sink to the bottom. The lighter waste stays at the top and is washed off the end of the jig. The barite is removed from the bottom by what are called "cups." A cup is a pipe about 1 cm above the screen to the top of the jig. The barite fills the pipe from the bottom. The material is then removed by a series of pipe or slides. In some cases, jigs are used in series to upgrade the material. There must be a difference in the specific gravity between the waste product and the barite for this method to work. In Nevada, jigs are used to separate waste from ore. The waste material has a specific gravity of about 2.75, while that of the barite ore is greater than 4.20. Figure 2 is a diagram of a typical jig plant.

Spirals and Tables

Spirals and tables are used infrequently because of the cost to operate the units. Both methods use specific gravity and the material movement to separate the waste from the ore.

Flotation

Flotation can also be used to separate the waste from the barite. This method is used when the liberation size is finer than what a jig or other equipment can handle. Normally, the feed for a flotation cell is 40 mesh or finer. The flotation method uses a chemical to float either the barite or waste into a froth. The separated barite is normally called a filter cake, because a filter is used to remove the excess water from the barite.

MARKETING

Uses and Specifications

According to the USGS (Searls 2004), during 2003, approximately 95% of all the barite mined and processed in the United States was used by the petroleum industry. The remaining 5% was used by the industrial market and the medical field.

In the petroleum industry, the barite is used to make what is known as "drilling mud." Barite and other additives in drilling mud assist in several ways during drilling. The barite serves as a weighting material that increases the hydrostatic pressure of the drilling mud and thus controls high-pressure zones that are encountered during drilling. Proper weighting prevents what industry calls a "blowout." Because the barite is soft, it does not damage or cause abrasion problems to drilling tools such as the bits and drill pipe. Also because of its softness, it will also act much like a lubricant. Finally, because barite is chemically inert, it does not react with or interfere with other components used in the mud.

The American Petroleum Institute (API) has set specifications for the barite used in the oil industry. These specifications primarily deal with specific gravity, particle size, and maximum quantities of some impurities. The barite must have a minimum specific gravity of 4.20 g/cm³. It must also be ground to a powder where at least 97% will go through a 200 mesh sieve. The amount of water-soluble alkaline earth metals must be below a prescribed amount, 250 mg/kg. In addition to the specifications set by API, the barite used in the drilling fluids on the offshore drilling rigs in the Gulf of Mexico must meet specifications set by the U.S. Environmental Protection Agency (EPA) on mercury and cadmium content.

Barite is used in the industrial market in such products as traffic cones; brake linings; paint; sound-deadening materials in automobiles, golf balls, and foam; and as filler in several other products. The barite specifications for industrial products also involve specific gravity, particle size, and quantities of impurities. Some of these products have an additional specification for brightness or whiteness. The barite specifications vary depending on the needs required by the final product. For example, the barite in automobile brake lin-

Figure 2. Typical jig plant

ing normally has a specific gravity of 4.35 or higher. A barite with higher specific gravity normally contains fewer impurities such as quartz. The lower quartz or silica content results in a higher-quality brake lining because quartz is very abrasive. In addition, many of the industrial products have a specification on maximum particle size. The maximum particle size is important in some products such as brake pads and sound-deadening sheets that have a particular thickness. If the ground barite is larger than the thickness of the material, it could cause holes in the product. Color can be a factor in the sound-deadening barriers for automobiles if it is visible. Color can also be a factor to a paint manufacturer. In paint applications, a very white barite with a high brightness is preferred because it is easier to tint or control the final color of the product. In the paint industry, grind size of the barite is also important because particle fineness will affect paint gloss. An instrument used in the paint industry, a Hegman gauge, is used to determine the maximum size and fineness of the ground barite.

The medical industry uses barite that has been through a special process that produces a very high-purity barite. This barite is used in lower and upper gastrointestinal tests. Because barite is dense, x-rays do not penetrate the material and it shows up on the x-ray. The mineral witherite, which is a barium carbonate, cannot be used by the medical profession because it dissolves in water and is poisonous to humans.

Therefore, not all barite deposits are suited for every barite use. If one is looking for barite for use in the paint industry, one would need to locate a deposit that has a high whiteness and brightness. The material would need to have a specific gravity exceeding 4.35 and also a low calcium and silica content. The deposit should not have minerals or contaminants that would cause the barite to become discolored. For example, the barite in Georgia is white, but iron oxide is present, which causes the final product to be light brown. Barite that meets the high-purity, high-gravity, and high-brightness/whiteness standards is normally referred to as paint-grade barite. The value of paint-grade barite is much higher than drilling fluid-grade barite because of these requirements.

A barite with a specific gravity that exceeds 4.35 but has an associated mineral that results in a lower brightness or whiteness may be ideal for the brake industry. This material, however, would also need to be low in silica and calcium content to be usable in the brake industry.

Barite deposits useful for oil and gas drilling must have barite that can be separated to give a minimum specific gravity of at least 4.20. The color of the barite is not a factor. The deposit must be low in mercury, cadmium, and water-soluble alkaline earth metals to be usable for offshore drilling rigs. The selling price of crude drilling-grade barite is relatively low. Therefore, processing and

transportation costs are leading factors in determining whether a deposit is economic.

Competitive Substitutes

As reported by the USGS (Searls 2004), alternatives to barite in the drilling market include celestite, ilmenite, iron ore, and synthetic hematite. Normally, iron ore, ilmenite, or hematite is used when a drilling mud with a very high density is required. All three minerals have a higher density than barite. Ilmenite, iron ore, and hematite are also harder than barite. The greater hardness of these minerals can result in higher wear than experienced with barite. Celestite has the same hardness as barite, but is lower in density. None of these minerals have had a major impact on the barite usage in the drilling-fluid industry.

The industrial sound-deadening market can use calcium carbonate instead of barite when the thickness of the sound-deadening sheet is not an issue.

Packaging and Transportation

Crude barite is normally transported by ship, barge, rail, and/or truck. In most cases, the material is transported from the mine to its final destination by a combination of several different modes. The means of travel depends greatly on what types of transportation are available in the area. Crude ore is generally transported in open-top barges, railcars, or trucks. In the case of white barite, which is used in the filler industry, special care must be taken to prevent color contamination. Therefore, the barite is transported in barges and railcars with tops to prevent contamination from river water and other possible contaminants.

The finished barite in the drilling fluid market is normally sold in bulk, bulk sacks, or paper bags. In the United States, the majority is shipped in bulk by truck, rail, ship, or barge. Paper bags are the second most popular means of packaging, followed by bulk super-sacks. Because a large amount is shipped in bulk, temporary silos are used at the oil well sites to hold the bulk material. Grinding plants and warehouse locations have large bulk silos with warehouse space for bagged material. The bag material is normally labeled with lot numbers that relate to production dates and quality records. Bulk shipments can also be traced to production and quality records.

In the industrial/filler barite market, the finished barite is also sold and shipped in bulk, bulk sacks, and paper bags. Bulk is still a major way that the barite is sold, but paper sacks and bulk sacks are playing a much bigger role. Many industrial barite consumers use batch methods to make their products, and paper bags fit their needs better than large bulk silos. Most of this barite is shipped by truck. Generally, every truckload is certified individually with the lot number and quality results recorded.

Economics or Competitive Factors

The United States imports barite from several different sources. Today, much of the imported barite is from China and India. The duty and fees associated with importing barite must be taken into consideration. The current costs of these fees can be obtained by contacting the U.S. Customs and Border Protection (CBP) agency. The fees can change; therefore, it is recommended that one check the current rate with CBP. The product CAS (Chemical Abstracts Service) numbers, such as 2511.1-05000 for crude barite and 2511.10.1000 for ground barite, are required.

Each country has different import requirements, and some countries have barriers to stop or restrict barite import. These requirements and laws can change rapidly, so it is best to check with the country's custom officials to determine current laws pertaining to barite import and export.

When determining the economics of a barite deposit, one must consider not only the cost to mine and process the ore but also the cost to obtain proper permits. Mining laws can vary for every country and every state or province of that country. When evaluating a barite deposit, a copy of current mining law for that country or state should be obtained. Local government officials should be able to explain which permits are required to perform exploration and/or mining in the area. In most cases, the governing agency will require a mining and reclamation plan to obtain a mining or exploration permit, and possibly several environmental and area impact studies will be required. These could include cultural, archaeological, animal habitat, and water usage studies of the effect of the ore on rain runoff and dam safety, and assessments of the effect of the mining on groundwater and any other environmental issues pertaining to that area. When a permit is issued, a bond is required prior to any disturbance of the area. The bonding amount required in many cases will be equal to or slightly greater than the amount estimated to complete the reclamation of the planned disturbed area. Depending on the size of the project and government permitting requirements, it could take anywhere from a few months to several years to obtain the permits required to begin the exploration and/or mining of a deposit.

The initial study of a deposit can determine the type of mining required to retrieve the ore and a rough idea of the method required to process the ore. A rough estimate of mining and processing costs can be estimated from this information.

Other costs that need to be considered when determining the economics of a deposit include the cost to maintain the permits, the cost of any testing or monitoring required by a permit, the cost of utilities, the cost of operating the processing plant, the cost of labor in the area, the cost to acquire the property, and the cost for the mineral right by purchase or royalties. Another item to consider is the revenue that the processed ore will generate. If a competitor locates a deposit where the mining or processing gives them a price advantage, this advantage could affect the amount of revenue that would be received from the finished ore. Also, if the total demand were to drop and affect the total tons produced and sold, this would affect the cost structure of the operation.

REGULATORY AND ENVIRONMENTAL CONSIDERATIONS

Environmental, Health, and Safety

As mentioned before, minerals associated with the ore are a main concern when mining and processing barite. In many barite deposits, quartz is present with the barite. If the level of quartz is high enough, the ore must be handled so as to reduce the respirable silica level. Dust masks may be required when processing and handling some barite because of the silica level. Water trucks are used during mining to reduce the amount of dust in the air.

If unoxidized minerals such as pyrite are present with the barite, acid mine drainage or low-pH runoff could result from groundwater or storm water contact with the pyrite. The acidic runoff may also leach additional minerals from the ore, resulting in runoff with a low pH and high minerals concentration. Both the runoff of this water as well as the accumulation of this water in mining pits are of possible environmental concern. These issues must be addressed within the context of the environmental requirements in place in the jurisdiction within which the mining occurs.

Reclamation

After the exploration and/or mining has been completed, reclamation of the disturbed areas must be performed. Generally, open pits are left open with fences along the high walls for safety reasons. In some areas, where acid mine runoff is not a concern, the mining pit

will fill with water, forming a lake that can be used for recreation purposes or wildlife habitat. In some rare cases, the mining pits are backfilled to prevent the mine from filling with water. The area is sloped to blend with the surroundings. Under ground mining entrances are sealed to prevent entrance by unauthorized personnel. The waste piles are sloped to a 3:1 ratio to minimize erosion. The slopes may also have earthen terraces to minimize the effects of runoff. After the area has been sloped, it is planted with an assortment of local vegetation. Using plants not native to the area is not recommended unless approved by the governing agency. There have been several cases in history when non-native plants have caused major problems.

Haul roads, trenches, plants sites, and other disturbances are sloped to blend with the surrounding topography and seeded. All buildings are dismantled, and water wells are sealed.

Closure and Decommissioning

The appropriate governing agency will monitor progress during reclamation. Often, the amount of bonding can be reduced as some areas are completed. When the total area is completed, a request can be submitted to close the operation and release all bonding. The amount of time required to complete the closure process will vary. The governing agency will want to make sure that the vegetation is well established and that all runoff is controlled. They will also want to determine if the water discharge from that area meets their requirements. Areas deemed by an inspector as not meeting the requirements may have to be reworked. After the agency has determined that the area is stable and up to requirements, the complete bonding is then released.

Variations

In the United States, each state has different methods for handling bonding and release. Also, some states require special permits for water dams, which will affect the tailing ponds used in the jig and flotation methods. Some states restrict the amount of land that can be reclaimed for a particular end use. For example, Missouri will not allow more than 10% of the disturbed area to be used for wildlife habitat. In addition, a 3:1 slope is widely accepted for reclaimed land, but on some occasions, other slopes are used because of local requirements or variances. Some barite deposits may be located in air-sensitive zones where the air emission requirements are much more restrictive. These are just some of the possible variances that can be encountered concerning environmental, health, and safety issues. Local governmental agencies will be able to supply information on the requirements for their area.

Many countries around the world have regulations and requirements very similar to those in the United States. A few countries have mining regulations that are not as strict or as demanding as those in the United States and other countries. Regulations for each country of interest can be obtained from the governmental agency dealing with mining.

OUTLOOK AND FUTURE TRENDS

The use of barite has been historically tied to the oil industry because more than 95% of the produced barite is used in that

market. As the price of crude oil increases, normally there is more activity in the search for new oil fields. Greater activity means that more barite is needed for the drilling mud used in oil exploration. With the price of crude oil reaching all-time highs in 2004 and with predictions that worldwide oil consumption will increase by about 2% annually, the immediate future for the barite industry appears to be good. The long-term future of barite usage in the petroleum market depends on the development and use of alternate energy sources and how such use will affect the oil industry. The development of new energy sources that will lower the demand for crude oil should also decrease the demand for barite. The barite market would also be affected if a replacement for barite could be located. Of course, any replacement material for the oil business would need to be as soft as barite to prevent excessive wear, have sufficient weight to be an effective weighting material, and be chemically inert so that it would not harm the environment.

The other 5% of the barite market is for industrial uses. The largest user in this market is the automotive-related industry. Their uses include sound-deadening materials, brake linings, and automotive paint. The demand or the lack of demand for new automobiles affects this market. The new automobile market is consumer driven. Part of the brake market is for after-market or replacement-type parts. As a result, part of the brake market is driven by new car production, and part is driven by car maintenance. A possible indicator for the automotive market is the information released by the automakers concerning plant closures, layoffs, callbacks, and manufacturing expansions.

Bauxite

Vincent G. Hill and Errol D. Sehnke

Bauxite is the primary raw material used to produce aluminum metal. In addition to this dominant industrial end use are a number of very significant nonmetallurgical applications for bauxite-based and -sourced materials. These specialty applications include such critical industrial uses as abrasives, cements, chemicals, and refractories. Bauxite used in producing end products for these and other specialty applications must meet more stringent compositional and physical requirements than the crude ore commonly employed for aluminum production. Although there are substantial bauxite resources in the world, premium-grade bauxite ores suitable for use in these special niche markets have, over time, been limited to a few principal sources, such as China and Guyana. Precluding any major disruptions within these leading producer nations, adequate supplies of nonmetallurgical-grade bauxite are expected to be available to satisfy worldwide demand well into the next century. Now, as in the future, it is presumed that basic raw material costs will remain the determining factor controlling the economic competitiveness of bauxite-based products in the diverse and extremely competitive industrial minerals sector of the international marketplace. Furthermore, there appears to be an increasing trend toward supplying alumina (Al_2O_3), the refined form of bauxite, to meet ever more demanding high-end requirements in the world's nonmetallurgical markets. Under these circumstances, metallurgical-grade bauxite is being increasingly refined into specialty-grade alumina in production facilities that have been specifically modified to produce high-purity alumina for these rapidly expanding markets.

Bauxite is a naturally occurring, heterogeneous weathering product composed primarily of one or more aluminum hydroxide minerals, plus various mixtures of silica (SiO_2), iron oxide (Fe_2O_3), titania (TiO_2), aluminosilicate (clay, etc.), and other impurities in minor or trace amounts (Shaffer 1975, 1983; Patterson et al. 1986). The principal aluminum hydroxide minerals found in varying proportions within bauxite are gibbsite, $\text{Al}(\text{OH})_3$, and the polymorphs boehmite and diasporite, both $\text{AlO}(\text{OH})$. Table 1 gives selected properties of these principal bauxite minerals.

Bauxite is typically classified according to its intended commercial application: abrasive, chemical, metallurgical, refractory, and so forth (Andrews 1984; Hill 1994). Of all bauxite mined, approximately 85% is ultimately converted into aluminum metal; an additional 10% goes to nonmetal uses, such as various forms of alumina, the oxide of aluminum; and the remaining 5% goes to nonmetallurgical-grade bauxite applications (Figure 1). As

a result, the bulk of bauxite produced in the world is currently used as feed for manufacturing alumina via the wet-chemical caustic-leach method commonly known as the Bayer process. Subsequently, the majority of the resulting alumina is in turn employed as the feedstock for the production of aluminum metal by the electrolytic reduction of alumina in a molten bath of natural or synthetic cryolite (Na_3AlF_6). This is called the Hall-Héroult process. Depending on the grade and mineralogy of the bauxite used, the industry standard is that it takes approximately 4–6 t of dried bauxite to produce 2 t of alumina, which in turn yields 1 t of aluminum metal. In current market terms, the approximate value for 0.45 kg (1 lb) of each of these aluminum industry products, in U.S. dollars, is as follows: \$0.01 for metallurgical-grade bauxite, \$0.10 for alumina, and \$0.75 for primary aluminum metal. It should be noted here that, within the industry, the term *metallurgical grade* refers to bauxite conventionally used to produce alumina via the Bayer process and thus is primarily for aluminum production.

Beyond this use of bauxite—to produce primary aluminum metal—lies the critical area of nonmetallurgical or specialty applications that quantitatively comprise about 5% of total worldwide crude ore production. Precise figures on worldwide bauxite production and consumption levels within nonmetallurgical markets are not commonly available on a systematic or routine basis for collection and analysis. It is currently accepted, however, that the principal industrial end uses for nonmetallurgical-grade bauxite, ranked in order of total market value, are in the refractories and abrasives fields. In addition, the cement, chemical, and steel industries also consume significant quantities of bauxite for other industrial applications (Clarke 1977; Harben and Dickson 1983; Benbow 1988; Bolger 1997; Crossley 2001; Taylor 2003c). Furthermore, a wide variety of high-quality abrasive, ceramic, chemical, and refractory products are also produced directly from bauxite-derived, specialty-grade Bayer process alumina (Figure 1). This recently growing and expanding group of high-quality, high-end products includes

- Aluminum chemicals (e.g., aluminum fluoride, aluminum sulfate, and sodium aluminate)
- Flame retardants, fillers, and pigments for various paint, paper, plastic, and polymer products
- Activated aluminas for adsorbents, desiccants, catalysts, and catalyst supports
- Calcined aluminas for abrasives, ceramics, and refractories

Table 1. Properties of major bauxite minerals

Chemical Composition	Gibbsite, $\text{Al}(\text{OH})_3$ or $\text{Al}_2\text{O}_3 \cdot 3\text{H}_2\text{O}$	Boehmite, $\text{AlO}(\text{OH})$ or $\text{Al}_2\text{O}_3 \cdot \text{H}_2\text{O}$	Diaspore, $\text{AlO}(\text{OH})$ or $\text{Al}_2\text{O}_3 \cdot \text{H}_2\text{O}$
Al_2O_3 content, wt %	65.35	84.97	84.98

* Diaspore differs from boehmite by having a more closely packed and tightly bonded atomic structure.

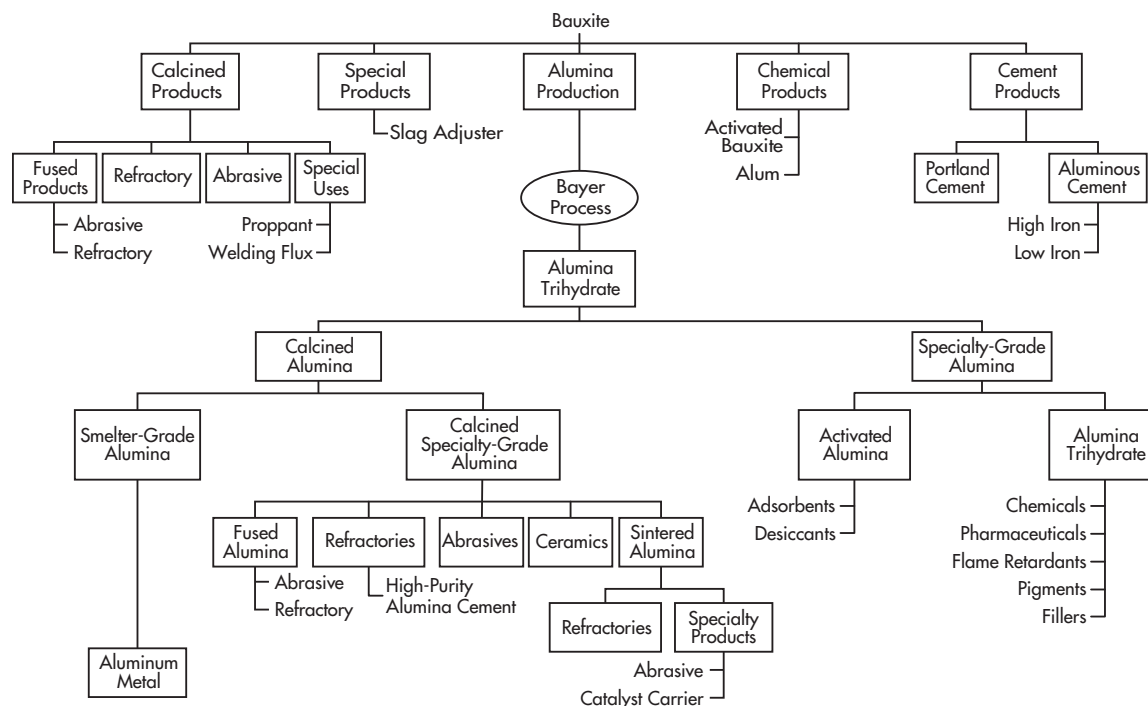

Figure 1. Aluminum industry flow diagram

- Hard-burned (sintered) calcined aluminas to produce tabular alumina, principally for high-performance refractory materials
- Fused aluminas, mainly for abrasives and refractories

This generalized aluminum industry flow diagram, from bauxite ore through alumina production to aluminum metal, gives a broad overview of the numerous products and end uses that are derived from bauxite.

The rock name *bauxite* was first used in 1845 for an earthy, red rock that had been discovered in 1821 by Pierre Berthier, a French chemist, close to the small village of Les Baux de Provence in southern France. Berthier's initial data suggested that this material was an alumina hydrate with two molecules of water. It was subsequently determined by thermal analysis, however, that the substance was a mixture of monohydrate and trihydrate minerals, as well as minor amounts of iron oxides, clays, and fine-crystalline silica. Diaspore had been discovered in 1801 and gibbsite in 1822. The rock name was, however, retained for this impure mixture of aluminous minerals. When the name of the village was changed to Les Baux around 1885, Sainte Claire De ville suggested that the

rock name should reflect this, and it was changed to the term known today—bauxite (Bracewell 1962; Regnier 1988).

In 2002, the most recent year for which complete annual production data are available, 22 countries reported bauxite mine production, and total world production amounted to 144 Mt of bauxite. This was an increase of 5% over 2001 production. The U.S. Geological Survey (USGS) estimates the 2003 total world bauxite production, from a similar number of producing nations, as essentially unchanged from that for 2002. Australia, Guinea, Jamaica, Brazil, and China, in order of volume, accounted for slightly more than 75% of the total bauxite mined during 2002, with a similar volume projected for 2003 (Plunkert 2004). In terms of nonmetallurgical-grade bauxite production, the principal sources of supply presently are very limited and comprise only a handful of possible source nations; that is, abrasive grade: Australia, China, Greece, Guinea, Guyana, and Italy; and refractory grade—Brazil, China, and Guyana. In addition, with the current world bauxite production at the 144-Mt level, the size of the total world nonmetallurgical bauxite sector is estimated at 7.2 Mtpy.

Total known world reserves for all types of bauxite are sufficient to meet cumulative world aluminum metal demand well into the next century. Although bauxite reserves are known to occur in as many as 50 different countries, nearly 90% of the reserves occur in only a dozen countries. The sheer magnitude of these reserves (23 billion t) is sufficient to ensure a readily accessible supply for the future (Table 2).

Past estimates of world bauxite reserves were about 1 billion t in 1945, almost 3 billion t by 1955, nearly 6 billion t in 1965, about 17 billion t in 1975, approximately 21 billion t by 1985, and roughly 23 billion t in 1995. It is expected that in 2005 the estimate of total world bauxite reserves will remain near or be slightly above the 1995 level of 23 billion t. Currently, Guinea, with 7.4 billion t of bauxite reserves, and Australia, with 4.4 billion t, together possess approximately one-half of the world's known reserves. Growth in reserves has more or less paralleled the expansion of world bauxite production capacity. Although major new discoveries are the primary factor in reserve increases, production economies resulting from technological advances and large-scale operations have also permitted the inclusion of lower grade bauxite previously considered subeconomic. In the early 1990s, it was reported that there were at least 211 known bauxite deposits in the world containing a minimum of 1 Mt of reserves (Roullier 1990; Bárdossy and Bourke 1993). Considering the added probability of discovering additional bauxite deposits, plus the likely possibility of employing lower grade bauxitic materials and other alternative sources of alumina, resources for the production of aluminum metal remain adequate to satisfy demand well into the future. The case is not quite as compelling for nonmetallurgical grades of bauxite, which normally must meet very rigorous quality requirements and are supplied from a markedly smaller number of worldwide sources. Even so, precluding any major disruptions within the small number of current producer nations, adequate reserves of nonmetallurgical-grade bauxite are available to satisfy probable future worldwide industrial demand (Table 2).

The annual world "in place" nonmetallurgical-grade bauxite mine production capacity at the end of 2003 was estimated at approximately 8.1 Mt, about 5% of the estimated total worldwide crude bauxite production capacity (Table 3).

Table 4 lists the principal nonmetallurgical-grade bauxite producers of the world for 2003.

GEOLOGY

Aluminum is the earth's most abundant metallic element, making up approximately 8% of the planet's crust; it is present in virtually every common rock type. Consequently, the derivation of bauxite is extremely variable and includes a wide variety of source rocks. It is principally a weathering product formed as residual deposits at or near the earth's surface under tropical or subtropical weathering conditions. As such, bauxite is classified as a specific type of laterite, a highly weathered residual subsoil or material rich in secondary oxides of iron, aluminum, or both, nearly devoid of primary silicates, and commonly containing quartz and kaolin. The formation of laterite is the direct result of intense chemical weathering, or degradation, of preexisting rock units. When this weathered rock is enriched in iron oxides and hydroxides, it is termed *ferruginous laterite*. If, however, it is enriched in aluminum hydroxides, such as gibbsite, boehmite, or diaspore, it is termed *bauxite*. As might be expected, there is commonly a complete compositional continuum of these weathering products extending from ferruginous laterite, through aluminous laterite and bauxitic laterite to bauxite, depending on the amount of aluminum versus iron enrichment.

In the weathering process, aluminum is retained in aluminum hydroxide minerals while other constituents are leached from the parent rock. Throughout geologic time, conditions favorable for formation of bauxite existed in areas and geological periods that provided warm, wet climates with alternating wet and dry periods; aluminous parent rocks with high permeability and readily soluble minerals; good subsurface drainage; and long periods of tectonic stability which permitted deep weathering and preservation of residual land surfaces.

Bauxite has formed intermittently throughout most of geologic history, from the Precambrian to the present. This "bauxitization" process, and the preservation of its products, appears to have been more intense during certain periods than others and more than three-fourths of the world's bauxite resources occur in geologically young deposits. Moreover, most of these occurrences started to form in the late Tertiary or earlier, and continued to be enriched in aluminum throughout the Quaternary, with the conditions for their formation even persisting to the present. Throughout the Tertiary, conditions were particularly favorable for widespread laterization and the formation of many large, high-grade bauxite deposits. The deposits from this time tend to be predominately of gibbsitic composition with minor amounts of boehmite. During the Mesozoic, bauxite developed extensively on carbonate rocks in karst terrain predominately with boehmite and locally important diaspore, as well as minor gibbsite. Paleozoic bauxite deposits, mainly in the Devonian and Carboniferous periods, are more restricted and chiefly contain diaspore and boehmite minerals. A broad time relationship has been recognized with boehmite and diaspore tending to be more abundant in older bauxite deposits and gibbsite more dominant in the younger deposits. Commonly, diaspore is found to be far more abundant in Paleozoic bauxite than in more recent deposits, boehmite dominates in Mesozoic bauxite deposits, and gibbsite is the key mineral in Cenozoic deposits.

Mineralogy and Physical Properties

Although bauxite deposits contain a wide variety of minerals, most of the nonmetallurgical bauxite ores consist almost entirely of the aluminum hydroxide minerals, gibbsite, boehmite, and diaspore.

(Table 1). Mixtures of gibbsite and boehmite are common in all types of bauxite, boehmite and diasporite less common, and gibbsite and diasporite rare. In this regard, some high-grade refractory bauxite consists solely of gibbsite with minor amounts of kaolin [$\text{Al}_2\text{Si}_2\text{O}_5(\text{OH})_4$]. The common impurities found in both metallurgical and nonmetallurgical bauxite are aluminosilicate (clays, etc.), quartz (SiO_2), hematite (Fe_2O_3), goethite [$\text{FeO}(\text{OH})$], rutile (TiO_2), and anatase (TiO_2). The most common high-alumina clay minerals associated with bauxite are the kaolin group of minerals; however, illite and chlorite occur in small amounts in some deposits. Hematite and goethite are the most abundant iron impurities in many

bauxites and the principal reason for the red and brown colors that are characteristic of countless bauxite deposits. They often occur as nodules, as concretions, and as finely disseminated forms intergrown with aluminous minerals. Aluminum substitution for iron in goethite results in the formation of aluminous goethite that is known to occur in various bauxite deposits, especially in Jamaica and Suriname. In fact, the amount of alumina present in the form of aluminum substitution within goethite can reach substantial amounts, as much as 5%–7% in Jamaican ores and 9%–25% in various Surinamese deposits. Magnetite [$(\text{Fe}, \text{Mg})\text{Fe}_2\text{O}_4$] and ilmenite (FeTiO_3), also occur in some bauxites, particularly those that are

derived from mafic igneous rocks. The titanium minerals found in bauxite include the primary minerals ilmenite or rutile and titaniferous magnetite, and the secondary minerals anatase and leucosine (TiO_2) formed during weathering. Titaniferous hematite and sphene (CaTiSiO_5) have also been noted in some bauxite deposits (Patterson et al. 1986).

To be technically correct, it must be noted that the aluminum hydroxide minerals present in bauxite are true hydroxides and do not contain water of hydration, as frequently referred to in some older publications. Nevertheless, the commercial terms *trihydrate* and *monohydrate* are commonly used by industry to differentiate various types of bauxite (Table 1). Bauxite that is totally or nearly all gibbsite bearing is called a trihydrate ore; if boehmite or diasporite or mixtures of both are the dominant minerals, the bauxite is typically referred to as a monohydrate ore. If substantial amounts of both gibbsite and boehmite are present, the bauxite is commonly termed a "mixed ore" (Shaffer 1983).

Bauxite occurs in many different forms, and its physical properties, structure, and texture vary markedly between and within deposits. It may occur as botryoidal, brecciated, clayey, earthy, fine-grained to massive, nodular, platy, pisolitic or coarsely oolitic, saccharoidal, vermicular, or even vesicular forms. Additionally, the color of bauxite ranges widely, with the most common ones being shades of red and brown. In terms of other physical properties, the in-situ specific gravity of most bauxite is normally between 1.5–2.4, but some types have been found to be as high as 3.7. This wide range is principally the result of variations in porosity, amounts of iron-bearing minerals present, and types of bauxite minerals in the ore (Shaffer 1983; Patterson et al. 1986). With regard to hardness, diasporite usually has a greater hardness than either gibbsite or boehmite because of its tightly bonded and denser atomic structure.

Classification of Deposits

Bauxite deposits occur in an extremely wide variety of geologic circumstances and physical shape; consequently, many classifications have been proposed by geologists to describe the occurrence of bauxite. Bauxite deposits have been variously classified according to their chemical composition, geologic origin, mineral composition, texture, topographic position, underlying rock type, and mode of occurrence. Each of these classification schemes and several others that have been proposed based on other attributes have all added to the general knowledge of the world's bauxite deposits, and each has its own merits. The geology of bauxite deposits has been treated at great length by three excellent works to which readers are referred: Bárdossy 1982; Bárdossy and Aleva 1990; and Patterson et al. 1986.

A widely applied method of classification is to assign all bauxite to either karst or lateritic types or, as modified, to carbonate and silicate deposit types. Yet another classification system, which has also received wide acceptance, is based on the shapes and occurrences of bauxite deposits. A modification of this latter classification organizes the varied kinds of bauxite deposits into blanket, pocket, interlayered, and transported (detrital) deposit types (Figure 2).

Blanket deposits of bauxite and aluminous laterite occur at or near the earth's surface and consist of flat or nearly flat-lying layers of variable thickness and wide lateral extent (Figure 2A, B, C). Thickness may vary from 1 m or less to 40 m in special instances, although 4–6 m is the average. Laterally the layers may extend over an area covering many kilometers. The majority of these deposits are residual, having formed from underlying aluminosilicate-bearing rocks of varying types, and only a very few contain transported material. Overburden on these deposits may be absent or extend up

to 10 m in thickness. Large blanket deposits are known to occur in Australia, India, South America, and West Africa.

Pocket deposits occur principally as infillings of karst depressions formed on limestone and dolomite, but some are associated with other rock types (Figure 2D, E). They vary greatly in shape and volume. The size of these pocket deposit depressions may range in depth from less than 1.0 m to greater than 30 m. In some cases, the bauxite-filled depressions occur as isolated, independent bodies, while at other locations the depressions coalesce and contain large and extensive amounts of bauxite. They occur on the Caribbean Islands of Jamaica and Hispaniola, as well as across southern Europe.

Interlayered bauxite deposits occur as discontinuous beds and lenses interstratified in sedimentary or volcanic rocks, and in some cases, along the contact between igneous or metamorphic rocks and overlying younger units (Figure 2E, F). They normally formed at a weathering surface as one of the other types of bauxite deposits and subsequently were buried. Thus, they are mainly remnants of old residual blanket deposits that were covered by younger rocks, but they may also include transported bauxite that has been enclosed by sedimentary rocks. Interlayered bauxite deposits have been found in Brazil, China, Guyana, Russia, Suriname, the United States, and southern Europe.

Detrital bauxite deposits result from the accumulation and preservation of transported bauxite that has eroded from other deposits (Figure 2F). Examples of this type of deposit were known to occur in the now depleted bauxite mining areas of central Arkansas. Detrital deposits that overlie eroded aluminosilicate rocks have been termed Tikhvin-type deposits, named after a type locality in Russia, and are found at localities scattered throughout Eurasia and northern China.

Major Bauxite Provinces of the World

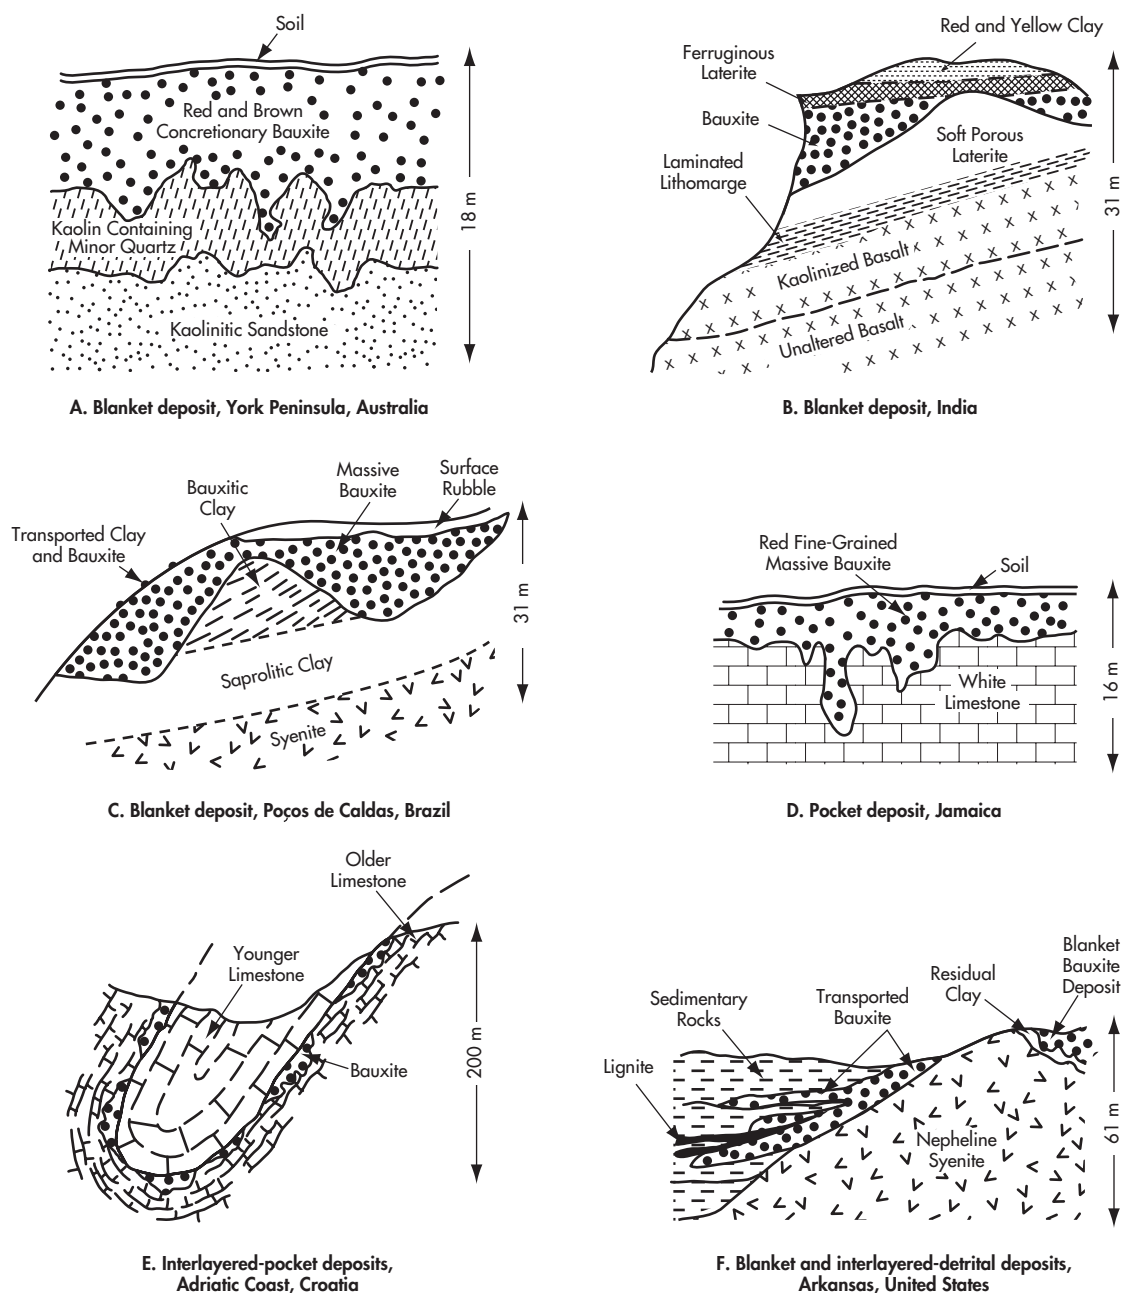

The major bauxite deposits of the world may be grouped into a series of provinces that are identified in the following sections and are shown in Figure 3.

As noted, bauxite is commonly divided or classified on its mode of occurrence and parent rock, as karst bauxite (deposits overlying weathered carbonate rocks) and lateritic bauxite (deposits derived from underlying aluminosilicate rocks). The first four provinces presented in this listing contain predominantly karst-type deposits, with the remaining four containing principally lateritic-type deposits. The areal extent and distribution of these bauxite provinces is as follows.

Caribbean Province

This province extends from Jamaica through Haiti and the Dominican Republic to Puerto Rico. The known deposits occur mainly as infillings in steep-walled depressions formed by the coalescence of typically uniform, vertical, cylindrical pipes that are located along intersecting faults in the limestone bedrock. Postdepositional faulting and erosion have resulted in the subsequent transport and deposition of the bauxite to form larger deposits. Metallurgical-grade bauxite is the principal bauxite produced from this province.

In Jamaica, the deposits fill sinkholes and channels and blanket uneven depressions in the karst surface of middle Tertiary age limestone. Individual ore bodies range from pockets containing a few hundred metric tons of bauxite to basins containing millions of metric tons. The soil overburden is only about 0.3–0.6 m thick. Jamaican bauxite in the plateau area is largely gibbsitic, with less than 3% boehmite. In contrast, the bauxite in the downfaulted blocks contains up to 20% boehmite, and aluminous goethite is the principal iron mineral. Ore grade is 45%–49% Al_2O_3 , 0.8%–8.0% SiO_2 , 17%–22% Fe_2O_3 , and 2.5% TiO_2 . Particle size varies from less than

Adapted from Patterson et al. 1986.

Figure 2. Typical occurrences of bauxite

1 to 40 μm . The bauxite deposits of the Dominican Republic and Haiti are similar in age, genesis, and grade, and are identified as a “Jamaican-type” or *terra rossa* bauxite, occurring as concentrations of soft, earthy material in karst depressions (Figure 2D).

Mediterranean Province

This province extends from Turkey through Greece, Albania, Serbia and Montenegro, Bosnia and Herzegovina, Croatia, Hungary,

Italy, and into France, with smaller associated deposits in Spain and Austria. The principal ore mineral is boehmite, although a few bauxite deposits contain a mixture of both boehmite and gibbsite—in an even smaller number, gibbsite is predominant (Hungary), and in others, significant amounts of diasporite are present (Turkey). This is the bauxite province in which bauxite mining and processing was first developed and put into production, and where bauxite is still mined by underground methods.

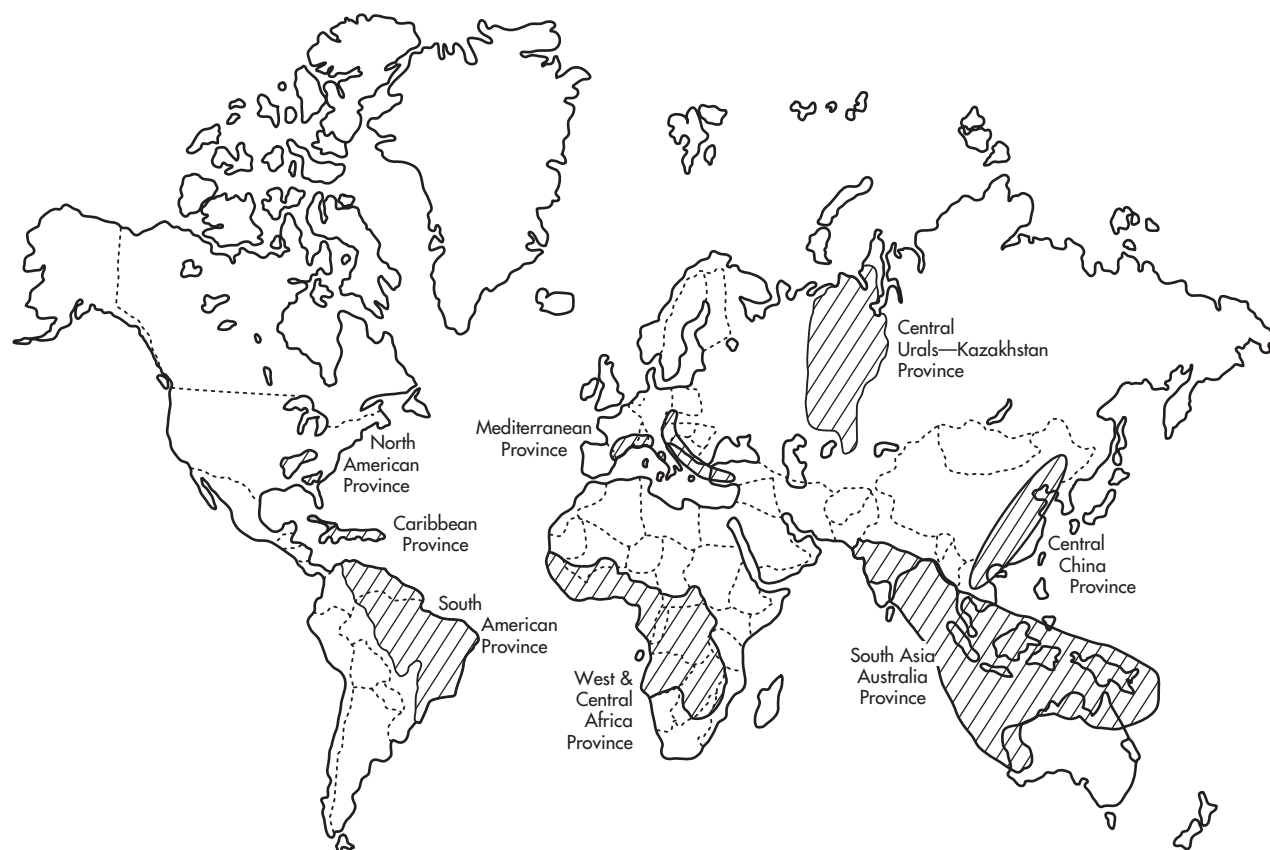

Figure 3. Major bauxite provinces

Many of the European deposits are associated with pockets and depressions in the karst weathering surface of Mesozoic carbonate beds that have been buried, folded, and faulted subsequent to the development of the bauxite (Figure 2E).

Central Urals—Kazakhstan Province

This province includes subsidiary occurrences in the Tikhvin area near Boksitogorsk, east of St. Petersburg on the northwestern margin of the Moscow Basin, and also areas in Ukraine. Deposits vary from bauxite horizons grading into bauxitic clay, and finally clay into a series of bauxite horizons in clay. The deposits in the Ural Mountains are mainly karst-type bauxites. The mineralogy varies from predominantly gibbsite in many areas of Kazakhstan to predominantly boehmite in the Urals. Much of the bauxite from this province is a high silica variety and low grade in comparison with ores from other parts of the world. The deposits in the Tikhvin district, the Urals, and Ukraine are relatively lower in silica content. Most of the mining in the Urals region is by underground methods, but open-pit mining methods are used in Kazakhstan and elsewhere.

China Province

This province extends from the Benxi-Fuxian region in Liaoning Province in northern China southwestward to Guangxi in southern China, and then into Vietnam. Most of the deposits occur in Carboniferous and Permian sedimentary rocks and consist chiefly of monohydrate-type bauxite, mainly diaspore, with significant amounts of boehmite, particularly in Guizhou Province and Vietnam. Virtually all the Chinese deposits either contain or are closely

associated with kaolinitic flint clay, which means that they have high reactive silica (aluminosilicate) levels. In fact, commercial definitions of what is actually termed bauxite differ between China and the rest of the world, with Chinese diasporic high-alumina clay being classified as “equivalent” to bauxite. China is noted for its nonmetallurgical-grade bauxite production, which is centered in Guizhou, Henan, Shandong, and Shanxi provinces.

African Province

This province comprises the Guinea and Cameroon shields. The Guinea Shield area extends from Guinea-Bissau to Ghana and northward into Burkina Faso and Mali. Deposits are part of an extensive area of laterization associated with Precambrian igneous basement terrain, and include a boehmite content of as much as 15%. The Cameroon Shield contains deposits developed on the extensively laterized terrain in this central African shield area. The continuation of this province extends southeastward from the South Atlantic coast across south-central Africa and beyond to Malawi and Mozambique.

In Guinea, the reported bauxite reserves are the largest known for any country in the world (Table 2) and mining is currently conducted in the Fria, Kindia, and Sangaredi districts. At the Fria deposit, the bauxite is composed of red gibbsitic earth with hard concretions, lumps, and crusts. Gibbsite is the principal bauxite mineral. The ore horizon is about 8–12 m thick and covered by a thin soil that is 0.1–0.2 m thick. Typical ore grade is 48% total Al_2O_3 , 21% Fe_2O_3 , and 2.5% SiO_2 , of which about 30% is very fine-grained quartz.

The D  b  l   deposit near Kindia is generally 6–8 m thick with a thin soil cover of between 0.3 and 0.5 m. Gibbsite is the principal ore mineral in the Kindia district. Typically, D  b  l   ore averages 48% Al_2O_3 and 1%–3% SiO_2 .

The large bauxite deposits of the Sangaredi district occur as lateritic caps on inland plateaus at elevations of about 275 m or more above sea level. The deposits have been dissected by stream drainage systems. Most of the bauxite is believed to have formed through weathering of Devonian or post-Devonian schists and sandstones. The thickness of the Sangaredi deposit averages more than 20 m and, before mining, exceeded 40 m in some locations. Overburden, where present, consists of thin topsoil. Typical ore contains 57%–60% Al_2O_3 , less than 1% SiO_2 , and 2%–4% Fe_2O_3 . When mining commenced in 1973, this was the richest single bauxite deposit known to exist anywhere in the world. The upper zone of the Sangaredi deposit contained only a few percent boehmite, but mining has now progressed to lower benches where the monohydrate content has increased to almost 10%. To extend the overall life of the mining project, operations have been expanded to the adjacent Bidikoum and Silidara ore bodies.

There are a number of large bauxite deposits known to be present in central Guinea, which remain undeveloped because of access and infrastructure issues. Extensive deposits occur in the Dabola and Tougu   districts with bauxites that reportedly contain 47%–52% Al_2O_3 and 3%–4% SiO_2 .

South Asia—Australian Province

This province consists of the Australian, Indian, and Southeast Asian subprovinces, described in the following paragraphs.

The Australian Subprovince includes Australia's major bauxite deposits of the Darling Range, Gove Peninsula, Mitchell Plateau, and Cape York Peninsula. These contain both in situ and transported materials that were deeply weathered during Cretaceous and Miocene times. The mineralogy is dominated by gibbsite, but a significant amount of boehmite is present.

The bauxite deposits of the Darling Range in Western Australia occur as a residual capping on Precambrian granite, gneiss, and intrusive crystalline rocks. They occur in a belt approximately 350 km long and 60 km wide located about 30 km inland and parallel to Australia's western coastline. A loose blanket of soil (0.3–0.6 m thick) mixed with loose pisolites covers the deposits. The upper portion of the ore is characterized by a ferruginous hardcap about 1.5 m in maximum thickness. The bauxite zone has an average thickness of about 4 m, but locally may be more than 12 m thick. The ore is characterized by a low alumina and high quartz-sand content; however, the reactive silica is typically less than 2%. General composition is 38%–46% Al_2O_3 , 10%–23% SiO_2 , 11%–16% Fe_2O_3 , and about 4% TiO_2 .

The Gove deposits in the Northern Territory are large lateritic-type bauxite deposits that underlie remnants of an undulating plateau of laterized sediments. Most deposits in the district are 3–4 m thick, but may range up to 10 m. The bauxite consists chiefly of gibbsite, but some boehmite is present, especially at shallow depths. Silica contents are low and occur mainly in kaolinite. A typical section of bauxite exposed by mining operations has 2 m of overburden, below which is 3 m of loose pisolitic bauxite, 1.5 m of cemented pisolitic bauxite, 1 m of tubular bauxite, and 5 m of ferruginous and siliceous barren laterite. The pisolites are usually about 5 mm in diameter. The normal grade for Gove bauxite is reported as 48.7% Al_2O_3 , 3.6% reactive silica, and 17% Fe_2O_3 (Shaffer 1983).

The major Weipa deposits in Queensland, Australia, occur in the upper portion of a flat lying to gently undulating laterite that

extends for more than 160 km along the western coastline of the Cape York Peninsula. The bauxite ranges in thickness from a few meters to nearly 10 m and is covered by a 0.3–1.0 m soil overburden (Figure 2A). Average ore thickness is about 4 m. The upper portion of the bauxite deposits contains spherical pisolites, which occur in a loose, reddish brown, silty sand matrix. The pisolites are normally 1–20 mm in diameter. Below the pisolitic bauxite there is a marked change to a zone of nodules and concretions usually high in iron and silica. The ore is a mixture of gibbsite and boehmite. The deposits are associated with underlying Tertiary kaolinitic sands, from which they were probably derived. The grade of the beneficiated bauxite is 53%–58% Al_2O_3 , 4%–7% SiO_2 , and 12% Fe_2O_3 .

Other significant Australian bauxite deposits are the extensive and undeveloped deposits of the Mitchell Plateau and nearby Cape Bougainville in the Kimberley region of Western Australia.

The Indian Subprovince includes the deposits of India in Andhra Pradesh, Bihar, Karnataka, Kerala, Madhya Pradesh, Maharashtra, Orissa, and the western state of Gujarat. Smaller deposits occur in Jammu and Kashmir, with additional occurrences in nearby Pakistan. Deposits are usually of the blanket type (Figure 2B) and are part of a widely developed lateritic terrain. Gibbsite dominates in this subprovince.

The Southeast Asian Subprovince includes the bauxite deposits in Malaysia and Indonesia. Gibbsite dominates, with goethite and some clay minerals being the principal impurities. Both in situ and transported bauxite are present, the latter associated with sediments fringing nepheline syenite intrusions.

North American Province

This province consists of the Arkansas region and the Appalachian Valley and Ridge province, plus the Coastal Plain region of the southeastern United States. These deposits are generally gibbsitic in nature. It should be noted here that the United States is no longer a major producer of bauxite, and, in recent times, domestic mines have supplied less than 1% of the U.S. requirement for bauxite. The only active bauxite mines remaining in the United States are surface operations in the southeastern United States that produce bauxitic materials, a natural mixture of bauxitic clay and bauxite with a very low iron oxide content, used primarily for the production of alumina calcines.

South American Province

This province includes the bauxite deposits associated with the Atlantic Shield, the Central Brazilian Shield, the Guiana Shield, and the recent sediments of the Amazon synclinal basin. This province extends from Colombia through Venezuela, Guyana, Suriname, and French Guiana into Brazil. Throughout this province, laterization developed on the extensive erosion surface that overlies Precambrian basement rocks. The province contains major reserves of nonmetallurgical bauxite.

Bauxite deposits in Guyana and Suriname are scattered throughout a narrow belt extending along the contact between the Precambrian crystalline rocks of the Guiana Shield and the sedimentary beds of Tertiary or later age that form the Atlantic Ocean coastal plain, an area roughly paralleling the coastline and ranging from 24 to 110 km. These deposits usually rest on kaolinitic clay and range from exposed outcrops to ore bodies overlain by as much as 60 m of sand and clay, although the average overburden is about 20 m. Other deposits of bauxite and laterite occur in these countries at higher elevations on hill and plateau tops south of the coastal belt. The principal alumina mineral is gibbsite and the ore is high grade; typically 55%–60% Al_2O_3 , 2%–5% SiO_2 , and less than 3% Fe_2O_3 . Both countries have been exporters of abrasive- and refractory-grade

bauxite, with Guyana known throughout the world as a premier producer of nonmetallurgical-grade bauxite.

In the large blanket deposits scattered throughout the Amazon Basin of northern Brazil, bauxite occurs as a residual capping on dissected plateaus a few hundred meters above the Amazon or other nearby rivers. The ore in these deposits has normally developed as two distinct horizons on unconsolidated Tertiary sediments and is usually covered by 4–10 m of yellow plastic clay. The upper zone consists of a layer up to 1.5 m thick of nodular gibbsitic bauxite that is rich in iron oxide and underlain by a similar thickness of hard, blocky, ferruginous, and siliceous concretions in clay or ferruginous laterite. The lower ore zone consists of a 1- to 7-m layer of hard, massive bauxite with clay seams and an underlying mottled kaolin clay. Ore thickness averages about 5 m. The approximate grade after washing is 55% Al_2O_3 , 3.5% SiO_2 , and 11% Fe_2O_3 . The bauxite in northern Brazil and Venezuela is of the gibbsitic type and contains only minor amounts of boehmite. In addition, several small- to medium-size deposits of nonmetallurgical-grade bauxite are known to occur in the Almeirim district of the lower Amazon Basin, Brazil.

The bauxite occurrences described in these eight broad geographical provinces hold most of the known bauxite reserves of the world, but there are minor areas outside of these regions that contain other, less significant, bauxite deposits.

TECHNOLOGY

The exploration and development of nonmetallurgical-grade bauxite deposits generally involves the same basic techniques as those employed for metallurgical-grade deposits.

Exploration and Evaluation Techniques

In the search for bauxite, the exploration geologist primarily focuses on areas where geological evidence indicates that conditions were favorable at one time for the formation of laterite. Regions where the paleoclimate was tropical in the geological past are deemed prime target areas because, as previously stated, laterite and bauxite are believed to have formed under similar tropical or subtropical weathering conditions. In these tropical areas, landforms that have remained tectonically stable and have been preserved from erosional destruction are considered to be very good bauxite exploration targets. Such weathered landforms or erosion remnants include mesas, plateaus, peneplains, base-leveled areas, gently rolling areas, or gradual slopes—all of which have or did have adequate drainage to promote the formation of bauxite (Schellmann 1975; Shaffer 1975, 1983).

The first stage of planning a bauxite exploration program usually entails a thorough study of the regional geology, physiography, and any previous reports on exploration or mining operations within the area of interest. The initial regional appraisal should include a review of topographic maps (rarely available for remote tropical areas), aerial photographs, satellite imagery, and mosaics prepared from airborne side-looking radar (SLR) surveys. In the Amazon Basin of Brazil, where extensive cloud cover and dense rain forest canopy masks the underlying land surface, SLR methods have proven effective in revealing the hidden topography. In some cases, geobotanical techniques using true- or false-color air photos and satellite images have been used to identify vegetation types associated with aluminous laterites (Henderson, Penfield, and Grubbs 1984).

After specific target areas have been defined, reconnaissance by helicopter or fixed-wing aircraft can provide valuable accessibility and logistical support information. Surface prospecting for float samples in river drainage systems has long been a reliable

guide in the discovery of bauxite deposits. Furthermore, vertical channel sampling of indurated and resistant outcrops exposed in stream valleys can often furnish the first positive identification of the presence of bauxite in an exploration area. Detailed evaluation and development require drilling, pitting, or trenching to provide samples for chemical analysis. Accurately recovering those samples, however, can be a major problem because of the widely variable physical nature of bauxite ores. Drilling equipment appropriate for drilling the soft terra rossa-type bauxites of the Caribbean area is completely unsuited for testing the hard massive diasporic deposits of China or Turkey. To overcome this problem, a wide variety of test pitting and drilling techniques have been employed to evaluate bauxite deposits. The drilling methods have included various percussion and rotary drilling systems, such as churn or cable-tool drills, rotary auger drills, rotary core drills with diamond or tungsten carbide bits using air or water to lift the cuttings, and reverse circulation or vacuum rotary drills. Detailed surface mapping and topographic surveying are essential to document drill-collar and test-pit locations and elevations. In the case of nonmetallurgical bauxite targets, development drilling is usually more closely spaced in order to facilitate selective mining of this high-quality material.

It is difficult, if not impossible, to visually identify the minerals present in bauxite because of their extremely fine particle size. Consequently, sophisticated laboratory techniques are required for their qualitative and quantitative analyses. As a result, exploration and development samples are usually shipped to well-equipped laboratories for detailed analysis. Before the early 1970s, exploration samples were analyzed for iron oxide, silica, titania, and loss on ignition (LOI), and the alumina content was mathematically estimated by difference. This information was supplemented by analyzing composite samples for minor constituents. The most significant determinations for bauxite are its alumina and silica contents. The available or extractable alumina and reactive silica were determined by laboratory bomb (autoclave) digestion tests for metallurgical-grade bauxite. The experience from these tests provided the background for evaluating and predicting the behavior of a particular bauxite in a specific Bayer process refining plant. Both total alumina and available alumina (alumina recoverable by low- and high-temperature Bayer processes) were normally determined. In addition to total silica, it was important to analyze for reactive silica because the latter combines with alumina and soda in the Bayer process to form insoluble sodium aluminum silicates that are lost as red mud in an alumina plant's waste stream.

The current availability of x-ray diffraction and x-ray fluorescence spectroscopy equipment with integrated computer systems now permit the rapid qualitative and quantitative determination of the mineralogy and chemical composition of a sample, which serve as the basis for the determination of a bauxite's Bayer plant processing characteristics.

The determination of the suitability or value of a particular bauxite to produce smelter-grade or specialty alumina basically depends on the amount of bauxite, caustic soda (NaOH), and energy consumed to produce 1 t of alumina. As previously indicated, this is principally controlled by the amount of available alumina and reactive silica present in the bauxite. Reactive silica contents of more than 8% are usually uneconomical for treatment by the normal Bayer process because approximately 1.1 units (weight unit) of alumina and 1.2 units of soda are lost for each unit of reactive silica in the ore (McCawley and Baumgardner 1985). The "average bauxite usage rate" and the "average caustic soda usage rate" are parameters developed by the alumina industry to assess the feasibility of employing a specific ore for use as a metallurgical-grade bauxite/Bayer refinery

Table 5. Ideal characteristics for metallurgical-grade bauxite (Bayer plant feed)

Ideal Grade Characteristic	Impact if Inadequate
Low "reactive silica" (>1.5%–<3.0%) (kaolinite)	Increases caustic usage, a critical operating cost factor.
High extractable alumina (>49%)	Increases capital and operating costs for mining, processing, and especially mud disposal (larger equipment, bigger containment dams, and increased materials handling).
Low organic carbon	Increases operating costs by reducing plant efficiency and lowers product quality. Alternatively increases capital costs by adding organics removal facility.
Low boehmite (<3%)	Precludes low-temperature processing that can increase capital and operating costs.
Low goethite (tolerable in a high-temperature plant or with high hematite)	Slows clarification, lowers product quality, and increases alumina loss via mud circuit. Increases capital (equipment size) and operating costs (plant efficiency).
Low moisture (can create dust nuisance if too low)	Increases capital costs (larger evaporation facility), fuel consumption, and shipping costs.
Iron content (ideally >5%–<15%)	Low iron can lower product quality. High iron dilutes alumina content of bauxite.
Low quartz	Increases maintenance costs (pipe wear). Increases caustic usage in high-temperature plants.
Low impurities and trace elements	Can lower process efficiency (sulfur, chlorine, calcium) and metal quality (gallium, zinc, vanadium, phosphorus)
Soft and friable	Increases mining and grinding costs.
Dissolves readily	Increases capital (larger digestion equipment) and operating costs (reduces plant efficiency, longer residence times).
Low titania	Can increase caustic usage in high-temperature plants.
Low carbonates	Can require special processing.

feedstock. In 1993, Bárdossy and Bourke presented a listing of 13 parameters they felt would define an "ideal" bauxite ore for use by a Bayer process refinery (Table 5). These are all critical factors that should be given detailed consideration during the determination of the economic viability of developing a bauxite deposit as a source to provide feed for a Bayer plant.

One important measure of the quality of a crude bauxite ore noted in Table 5 is the amount of organic carbon contaminants it contains; this is especially significant for the production of specialty-grade alumina products. During the Bayer processing of bauxite ores, organic carbon contaminants in the ores undergo degradation to sodium oxalate ($\text{Na}_2\text{C}_2\text{O}_4$) that builds up to equilibrium concentrations and remains in the recycled liquor of an alumina plant. In turn, this sodium oxalate in the leach liquors causes processing, disposal, and product quality problems during the production of alumina and, hence, must be removed from the leach solution when its concentration reaches the supersaturation point. Extensive amounts of research have been devoted to the best and most economical means for removal and disposal of sodium oxalate from Bayer refinery circuits.

Mining and Beneficiation

Bauxite mining is analogous to the mining or quarrying of other ores and industrial minerals, and does not employ any unusual or unique methods. Moreover, the mining of nonmetallurgical-grade bauxite consists of the same standard procedures and techniques that are customarily applied to the extraction of metallurgical-grade bauxite ores. In fact, in some cases, special quality grades of bauxite are selectively mined simultaneously with associated metallurgical ore-grade material. In these instances, the high-quality crude bauxite is stockpiled in separate holding areas to await the special handling and processing that is required for nonmetallurgical-grade raw materials (Everts 1984).

An industry survey conducted by the International Aluminium Institute found that mines producing metallurgical-grade

bauxite for export markets in 1998 generated about \$1.4 million in revenue per hectare mined, and a typical mining operation employed about 200 people for each million metric ton of bauxite produced (International Aluminium Institute 2000).

In recent years, 85%–90% of total world bauxite production has been by open-pit mining methods, with the remainder recovered from underground operations, principally in China, eastern and southern Europe, and Russia (Patterson et al. 1986; Martyn 1992). In open-pit operations, bauxite is normally extracted from strata typically 4–6 m thick under overburden that may range up to 10 m thick, covered by a thin layer of topsoil with its associated vegetation. At some nonmetallurgical mining sites, the overburden thickness may reach 70 m or more. In most instances, the topsoil is removed and stockpiled for use in reclamation programs at mine closure. Many ores are soft and sufficiently unconsolidated to be easily loosened and loaded by mechanized heavy equipment, while others consist of hard, dense bauxite requiring blasting to release and prepare the ore for recovery. Open-pit bauxite mining operations ordinarily employ various combinations of backhoes, bucket wheel excavators, bulldozers, draglines, power shovels, and scrapers for the stripping of overburden from the ore. In addition, draglines, front-end loaders, and power shovels are commonly used to excavate and load the crude ore. Loading is usually into haul trucks, or directly into rail cars or onto conveyor systems, for transport to bauxite processing facilities or stockpiles.

Depending on the nature of the bauxite, underground operations typically use a basic array of standard underground mining techniques, which include block caving combined with shrinkage stoping, sublevel stoping, top slicing, longwall, and room-and-pillar methods. Excessive water inflow is a significant problem at most of these mines, particularly in workings developed below the karst water table. In these cases, dewatering shafts are often drilled to lower the active water level at the mine site (Shaffer 1983).

Normally, the beneficiation or treatment of bauxite is typically limited to crushing, washing, and drying of the crude ore. After the

bauxite is mined, it is crushed and screened to remove fines, and in some instances is washed or wet screened to eliminate clay and silica contaminants. At a few special mining operations, heavy media separation techniques are employed to reduce the iron content or remove calcareous contaminants from the ore. Free moisture in crude bauxite, as mined, may range from 5% to 30%. Consequently, metallurgical and nonmetallurgical grades of bauxite that must be transported appreciable distances are normally dried before shipment. Drying facilitates the handling of some types of bauxite, and the degree to which a specific type of bauxite is dried depends in part on its individual handling and dusting characteristics. As indicated, because crude bauxite may contain substantial amounts of free moisture, drying results in savings on freight charges that may more than offset the drying costs. Bauxite from Guinea is usually dried to 3%–6% moisture, whereas Jamaican bauxite, because of its fine earthy nature and the potential to create dust problems, is shipped with about 15% moisture. Bauxite destined for use in abrasives and refractories is fired or calcined at 900°–1,650°C to remove both free moisture and chemically combined hydroxyl groups. Usually, abrasive grade material is calcined at around 1,100°C and refractory grade calcination is carried out at a higher temperature, generally about 1,650°C. For most other applications, the normal drying process entails heating crude bauxite in rotary drying kilns at about 300°–315°C, which removes most of the free moisture and produces dried bauxite ready for shipment. It is from this point that nonmetallurgical-grade bauxite undergoes special processing procedures to ensure it meets the strict market specifications demanded by individual end users.

Alumina Production

Practically all alumina produced commercially from bauxite is obtained via a process patented by Karl Josef Bayer in 1888. Although research on aluminum extraction from other mineral raw materials has continued for many years, this method has remained the standard for the industry. Bayer process refining of bauxite is the common starting point for the production of both smelter-grade and specialty aluminas (Figure 1). It employs a caustic leach of bauxite ore in a solution of sodium hydroxide (NaOH) at elevated temperature and pressure, followed by separation of the resulting sodium aluminate (NaAlO_2) solution and selective precipitation of the aluminum as aluminum hydroxide [$\text{Al}(\text{OH})_3$].

The actual processing conditions, such as the leach temperature, digestion holding time, and caustic concentration, as well as the operating costs, are greatly influenced by the type of bauxite to be processed. As a result, a Bayer alumina plant is designed to handle a specific type of ore and, without major plant modifications, ordinarily cannot efficiently process a bauxite that is markedly different from one that the refinery was originally designed to use. A listing of the preferred attributes sought in a metallurgical-grade bauxite and their impact on the efficiency of a Bayer refinery have been outlined in Table 5.

A Bayer process refinery is, in essence, a device for heating and cooling a large, continuously recirculating stream of caustic soda leach solution. Bauxite is added at the high-temperature point, red mud wastes are separated at an intermediate temperature, and alumina is precipitated at the low-temperature point in the cycle. The process is initiated by mixing crude or raw bauxite, which has been washed, and crushed or ground to 90% minus 10-mesh screen size with preheated, recycled, spent leach solution. Lime is added during this initial step to control the phosphorus content and to increase the solubility of alumina within the plant feed. The resulting slurry, containing 40%–50% solids, is pumped along with additional sodium hydroxide leach solution to pressurized digesters

where high-pressure steam is used to raise the temperature. Alumina and some of the silica are dissolved during this step, soluble sodium aluminate is formed, and a complex sodium aluminum silicate is precipitated from the process stream. Because these complex sodium aluminum silicate compounds represent a loss of both alumina and soda, a low reactive silica content is extremely desirable for metallurgical-grade bauxite ores.

Digestion, in digester vessels 3–4.5 m in diameter and up to about 30 m high, takes from 30 min to 8 hr, depending on the plant design and type of bauxite ore. Leaching temperatures may range from about 105°C to about 290°C, with most modern plants typically operating at between 200°C and 240°C, and corresponding pressures ranging from about 4,000 g/cm² to more than 15,000 g/cm². The lower temperature ranges are used for bauxite in which nearly all of the available alumina is present as gibbsite. The higher temperatures are required to digest bauxite having a large percentage of boehmite. Normally, at 140°C or less, only gibbsite and kaolin-group clay minerals are soluble in the caustic soda liquor, while at temperatures greater than 180°C, alumina present as monohydrate or trihydrate and also some alumina combined with clay minerals in the bauxite are recoverable and placed into solution. In terms of reactive silica, below 140°C only the silica in aluminosilicate minerals (clays, etc.) is soluble in the caustic soda solution, whereas above 180°C all or part of the free quartz present in the bauxite feed is also attacked by the liquor. Caustic concentration of the leach solution, expressed as grams per liter of caustic soda, usually ranges from approximately 170 to 400 gpl, depending on whether it is a low- or high-temperature Bayer refinery. The digestion of boehmitic bauxite requires stronger caustic concentrations, for longer holding times at higher pressures and temperatures, than gibbsitic ores (McCawley and Baumgardner 1985; Patterson et al. 1986).

The resulting slurry of sodium aluminate solution and insoluble red mud from the digesters is cooled to atmospheric boiling temperature, and a coarse sand waste fraction (mainly iron oxides and silica) is removed by gravity separators or wet cyclones. The fine solids in the red mud are then separated by decantation of the overflow in settling tanks measuring about 4.5 m in depth and 15 to 40 m in diameter. A flocculating agent such as starch is added to increase the settling rate of the red mud particles. These red mud wastes are then pumped to tailings ponds or containment areas for drying and final disposal. The pregnant overflow solution from these thickening tanks is further clarified by filtration and placed into precipitating tanks ranging in size from 8 to 9 m in diameter and up to 30 m in depth (McCawley and Baumgardner 1985).

In the precipitators, the clarified sodium aluminate-rich liquor is cooled until it becomes supersaturated at approximately 50°–70°C, then is seeded with fine crystals of aluminum hydroxide that initiate precipitation of alumina from the cycling flow of mechanically stirred liquor. The alumina is precipitated as alumina trihydrate, with the coarser fraction (typically >0.044 mm) separated by sedimentation or filtration, and washed (Taylor 2003a). The finer alumina fraction is recycled as nucleation seed for subsequent alumina crystallization, and the remaining spent leach solution containing some caustic soda is filtered and reconstituted and, together with the alumina remaining in solution, is recycled to the plant digesters. This regeneration of the soda lost in the process is ordinarily made up by adding caustic soda or soda ash (Na_2CO_3) and lime to the spent leach solution to bring it up to the appropriate caustic concentration before it is recycled. The majority of the filtered and washed alumina trihydrate is fired or calcined at between 1,000°C and 1,200°C to produce smelter-grade alumina for making aluminum metal. A smaller amount of the alumina, which is destined for some specialty markets, is calcined

at about 1,200°–1,400°C to convert the aluminum trihydrate into alpha alumina (α -Al₂O₃). The remaining portion of the washed alumina product may be left in trihydrate form for direct specialty alumina uses or it may be further purified and processed under controlled conditions to produce a variety of high-quality materials for uses other than metal production (Figure 1).

Over time, various modifications to the standard Bayer process have been attempted to resolve the problem of high silica levels in some bauxite ores. Bauxite containing 8%–15% reactive silica may be processed by either a soda-sinter process that is used directly on the high-silica bauxite feed or by a combination Bayer-sinter process applied to bauxite processing plant red mud waste streams. The largest numbers of modified processing plants in operation have been combination Bayer-sinter refineries where the high-silica bauxite is first subjected to a traditional Bayer caustic leach. The resulting red mud residue, containing sodium aluminum silicates, is sintered with limestone and soda ash. Then the sintered mass is leached with water to recover alumina and soda. In other instances where diasporic or other low-grade ores are encountered, as in China and Russia, a soda-sinter process is used to produce alumina. In this process, the low-grade bauxite is sintered with soda ash in rotary sintering kilns. This is followed by a water leach of the sinter residue and a carbon dioxide treatment of the resulting liquor to precipitate aluminum hydroxide. Additional desludging of the liquor is required, and this is achieved in a final autoclaving stage. Alumina produced by either the soda-sinter or combination process is relatively high-purity material and completely free from organic coloring matter and thus very white, so it commands a premium price in the specialty alumina market. In addition, the insoluble residue (brown mud) resulting from leaching the sintered materials has a composition somewhat similar to that of portland cement. The upper limit of reactive silica in bauxite for use by the combination Bayer-sinter process is about 15%. Both the soda-sinter and the combination Bayer-sinter processes are based on bauxite of marginal quality and require extensive amounts of energy, which make them unattractive candidates for widespread application around the world.

MARKETING

Commercial Applications

Nonmetallurgical-Grade Bauxite

The bauxite used for producing abrasive, chemical, and refractory products must meet much more rigid compositional requirements than the crude ore commonly used for aluminum metal production, as shown in Table 6.

Specifications for the premier grades of bauxite are based on the processing requirements and special properties required of their final commercial products. The natural chemical impurities that exist within these specialty-grade raw materials are not chemically removed from the ore during a refining procedure, as is the case with metallurgical-grade bauxite where impurities are eliminated through the Bayer process. Nonmetallurgical ores are used in an essentially unrefined chemical form, as a direct feedstock for the production of their ultimate end products.

The general chemical requirements for the principal classes of specialty-grade bauxite, as outlined in Table 6 and listed in terms of their increasing total alumina content within the raw or crude ore, are as follows

- Cement grade—moderate to moderately high alumina content, low silica. Iron oxide content may be high for production of some grades but should be low in grades requiring structural strength. Diaspore is preferred but not essential for this application.
- Abrasive grade—high alumina content, low silica, moderately low iron oxide, low titania. Iron is often added during the electric arc furnace fusion process to achieve correct iron oxide to silica ratios for formation of ferrosilicon slag.
- Chemical grade—high alumina content, should be gibbsitic ore, very low iron oxide and other acid-soluble oxides, silica (and clays) preferably low but not critical. The silica typically separates out as an insoluble residue during acid digestion; however, very high silica contents do substantially increase material handling costs. In some instances, this material is essentially equivalent to crude or green gibbsitic refractory-grade bauxite that has not been calcined.
- Refractory grade—high alumina content, low silica, low iron oxide, low titania, and very low alkalis.

As a side note, it must be pointed out that when analyzing statistics for these different raw materials and finished products (crude bauxite, dried bauxite, calcined product for abrasives and refractories, fused product, sintered product, etc.), they have different conversion factors from ore to product, and so are not equivalent on a weight-for-weight basis.

The principal nonmetallurgical-grade bauxite markets, in terms of value, are discussed in the following sections.

Refractory Applications

Refractories are commercial products created from heat-resistant materials that possess the capacity to maintain their form and

Table 7. Alumina-silica refractory products

Refractory Type	Raw Materials
Low-medium alumina (30%–50% Al ₂ O ₃)	Flint and semiflint fireclays, plastic and semiplastic fireclays, kaolin, and pyrophyllite
Medium-high alumina (50%–70% Al ₂ O ₃)	The andalusite-kyanite-sillimanite group of minerals, synthetic mullite, kaolin, and various bauxitic clays
High alumina (70%–90% Al ₂ O ₃)	Natural bauxite-based materials (calcined)
Extra-high alumina (90%–100% Al ₂ O ₃)	Calcined Bayer-process alumina, tabular alumina, and fused alumina

strength when subjected to highly elevated temperatures amid varying extremes of mechanical stress and chemical attack by hot gases, liquids, or molten and semimolten substances. In the modern economies of the world, alumina is the primary ingredient for a significant portion of the products used in high-temperature industrial applications. Alumina-based refractories are crucial components in nearly all high-temperature metallurgical, cement, ceramic, glass, and petrochemical manufacturing processes of modern industry (Crookston and Fitzpatrick 1983; Benbow 1989; Ramsahoye 1991; O'Driscoll 2001). The alumina content of a particular refractory may range from 30% to 100%, depending on the exact nature of raw material from which it is made and its intended application. The total spectrum of alumina-silica (Al₂O₃ + SiO₂) refractory products is delineated in Table 7.

Aside from the lower alumina categories, which are based primarily on clay minerals, and those products composed of natural aluminum silicate minerals [andalusite (Al₂SiO₅), kyanite (Al₂SiO₅), or sillimanite (Al₂SiO₅)], refractories containing more than 45%–50% alumina rely heavily on bauxite as the origin of their contained aluminum oxide. In general, the ability of an alumina-based material to resist high temperature increases with increasing alumina content.

By value, refractory applications remain the premiere non-metal market for bauxite. Some refractories with extra-high alumina content are produced directly from the premium quality alumina derived by processing metallurgical-grade bauxite ores (Figure 1 and Table 7), but the majority of standard refractory products incorporate a calcined or fire-treated form of bauxite for their raw material base. These natural bauxitic materials provide users of refractory products with a reasonably priced, high-alumina feedstock that is readily available and in relatively abundant supply.

Bauxite suitable for use in refractory applications must meet very stringent physicochemical requirements. To satisfy the high-temperature operating demands of quality refractory products, a

high alumina, low iron oxide content bauxite, generally with a 2.5% maximum Fe₂O₃ content after calcination, is required. The alumina content, on a calcined basis, should be at least 86.5%, although it is often closer to 90% for the highest quality products. To keep the formation of low-melting-temperature glasses to a minimum, only trace amounts of alkalis and alkaline earths should be present in the raw ore (0.02%–0.60% on a calcined basis). Excessive titania has an adverse impact on the high-temperature properties of fired shapes, and the titania content commonly must be limited to a 4% maximum in the calcined product. The silica content ought to be low, usually below 7.5%, but levels exceeding 10% may be acceptable; however, it should be present principally within a natural clay mineral and not as free quartz (Wittmer 1982; Andrews 1984). The typical range of chemical compositions and related physical properties that various producers cite for their calcined refractory bauxite are characterized in Table 8.

The final market acceptance of the bauxite for a refractory use is contingent upon the physical and chemical qualities of the commercial end product into which it is to be included or combined. The dimensional stability of fired refractories relies principally on the conversion of the contained alumina and silica within refractory raw materials to the highly stable corundum (α -Al₂O₃) and mullite (3Al₂O₃•2SiO₂ or Al₆Si₂O₁₃) mineral phases of these oxides (Schneider, Seifert-Kraus, and Majdic 1982). Strict control of the feedstock grade and calcination process to achieve these physicochemical conversions, and to maximize the density of the materials on a consistent and unvarying basis, are crucial to the production of quality refractory products (Everts 1984).

A number of physical tests are customarily applied to calcined products to assess their suitability for use as refractory raw materials. Chief among them are the following: determination of PCE, a measure of the material's softening or deformation temperature; measurement of bulk density; and calculation of apparent porosity. These are critical measurements that enable a manufacturer to

Source: Wefers and Misra 1987.

Figure 4. Transformation sequence—aluminum hydroxide minerals to alpha alumina

appraise the potential capability of a raw material to endure the very harsh operating environments continually encountered by refractory products. Because PCE is based on an alumina standard (a PCE of 42 for pure alumina), materials with greater alumina contents may be expected to have higher PCE values. Ordinarily this is the case; however, the presence of alkalis or alkaline earths will significantly decrease the PCE value of a refractory material and the resultant effect will be poor creep resistance in the final refractory product. Bulk density, which imparts a number of critical physical properties to the finished refractory, has also been found to fluctuate with the alumina content of the calcine. A high bulk density normally improves product resistance to shrinkage, hot load strength, cold crushing strength, hot modulus of rupture, and abrasion resistance but, at the same time, decreases the thermal shock resistance (Wittmer 1982). Low porosity, which correlates in a given material with high density, is also a highly valued attribute. It lends a defense against the encroachment of liquids or gases in harsh corrosive operating environments, thereby reducing the rate of erosion sustained by the refractory and increasing its functional life.

The green or raw bauxite that is judged to be of refractory grade is usually fired at temperatures in the range of 1,400°–1,800°C to transform the material into a combined corundum and mullite product. This roasting or firing procedure is termed “calcination,” and it is conventionally carried out in rotary or vertical kilns with the processed material undergoing very pronounced chemical and physical changes. During this intense heating process, all free moisture and chemically combined hydroxyl groups are expelled from the bauxite. The silicate minerals, present principally as clays, sustain solid-state changes and are transformed into mullite. This transformation is accompanied by the release of silica, which in turn combines with the additional amounts of alumina present within the bauxite to form further amounts of mullite. The

alumina minerals present within the bauxite (bayerite, boehmite, diaspore, gelatinous boehmite, gibbsite) experience a series of marked changes following the loss of the ir combined hydroxyl groups and they develop into transitional aluminas or “phases” (chi, eta, gamma, rho, et c.) prior to reaching the high-temperature-derived, alpha-alumina-crystal form (Figure 4).

A portion of this contained alumina is consumed by reaction with the liberated silica, as indicated previously, to form mullite, and the remainder of the aluminum oxide forms corundum (alpha alumina, the stable form of anhydrous alumina). The original alumina content of the crude bauxite is a primary determinant in the resulting total alpha-alumina content of the calcined product, and crude ores with the highest alumina levels produce calcines with the greatest corundum content. Perhaps one of the most significant points to note in Figure 4 is the relatively low temperature at which diaspore converts directly to alpha alumina, starting just above 500°C. This low conversion temperature has major implications on the energy input requirements for the production of a calcined product from bauxite with a high diaspore content. The entire series of phase changes results in an overall densification of the refractory product, and these transformations must be carried to total completion to prevent further shrinkage of the material during subsequent processing and its final utilization within high-temperature operating environments. When the calcination process is completed, the finished product has an aluminum oxide content of 86.5%–89.0%; in some cases it may even reach 90%, and the material has become so solid that its density is 3.10 g/cm³ or greater (Table 8). The optimum bulk density for most commercial applications is 3.25 g/cm³. After calcination, the final product should have maximum density and minimum porosity. Typically, 2 t of crude ore is required to produce approximately 1 t of calcined bauxite. In addition, the LOI of the calcined product is customarily less than 0.5% (Tables 8 and 9).

‡ Refractory A-grade Super-Calcined.

§ Not detected.

Following the calcination step and a subsequent cooling time, calcined refractory-grade bauxite is usually stored in enclosed areas for bulk shipment to its intended industrial markets. The calcined bauxite, which is normally in lump form at this stage, requires crushing, grinding, and sizing before its final use as a refractory product. At this point, maintaining a rigid control on the proportion of fines is of extreme importance because optimum refractory properties require a balanced particle size distribution. In its ultimate use as a refractory, the calcined bauxite product is mixed with binders and pressed, extruded, cast, and shaped into a variety of forms that are then dried and transferred to kilns for firing. The calcined refractory-grade bauxite is also used in unfired monolithic refractories (Shaffer 1983).

It should be noted here that another source of material suitable for use in refractory applications and products is the calcined bauxite used to produce brown fused alumina (Figure 1). Actually, it is estimated that 40%–50% of the brown fused alumina produced from calcined bauxite is used for refractories (O'Driscoll 2001). The chief advantage of fused alumina over other high-alumina refractory raw materials is its higher mechanical and chemical corrosion resistance. Currently, some degree of market growth is anticipated for brown fused alumina in the refractories sector.

Economic Considerations

The principal cost factors associated with the processing and producing calcined refractory-grade bauxite are acquisition of crude ore, labor wage rates, fuel charges, and transportation rates for the movement of the finished product to market. Because of the high energy requirements associated with the processing of these materials, the sensitivity of calcined materials to energy costs is of primary concern in the development and continued viability of refractory operations. This is demonstrated by the fact that the calcination phase of producing a quality high-alumina calcined bauxite (85%–90% Al₂O₃) requires approximately 13×10^6 Btu/t of product produced at a calcining temperature ranging from 1,700°C to 1,800°C (McMichael 1990). In addition, economy of scale plays an extremely crucial role in the cost of production for such bulk mining enterprises, and low costs are usually associated with the highly developed infrastructure and mechanization of large-scale metallurgical bauxite mining operations. This effectively imposes a limiting factor on the number of economically viable nonmetallurgical-grade deposits

capable of potentially providing refractory-grade raw materials for major international markets.

For refractory-grade bauxite, as with most industrial minerals, the basic commodity price is a crucial factor in the economics of development and continued maintenance of product markets. The trade-off between price and product performance is a primary determinant in the choice of refractory-grade bauxite, as opposed to various substitute materials in a variety of refractory applications. Examples of this price versus market tension are provided by synthetic mullite, created from kyanite and sillimanite, and refractory grogs, produced principally from kaolinitic clay, which constitute feasible product substitutes for medium-alumina-content bauxite-based refractories (Dickson 1982; McMichael 1990).

Sources of Supply

A limited number of bauxite ores have been found to meet the stringent physical and chemical specifications expected of refractory-grade bauxite, particularly within the very high-temperature fields encountered in most industrial applications. Consequently, the chief sources of refractory-grade bauxite traditionally have been limited to Guyana, followed by China, and more recently, Brazil. The highest quality materials have historically been supplied from South America, and, in particular, from mines in Guyana. As a result, because of its high quality, the RASC product from Guyana has frequently been used as a reference standard for comparison with calcined refractory bauxite from alternative sources of supply (Tables 8 and 9). In fact, until the late 1970s, refractory-grade bauxite from Guyana amounted to approximately 80% of the world's supply of this product. At that time, a combination of labor, technical, and mining difficulties within Guyana led to a severe market shortage that was only alleviated through the large-scale introduction of refractory raw materials from China into the North American and European markets. The world's refractory materials users accomplished this substitution in source of supply through some fundamental compromises and product adjustments. Chinese bauxite is composed primarily of diasporite [AlO(OH)], which has a greater hardness and, as a result, is more difficult to process than the Guyanese ore, which is composed principally of gibbsite [Al(OH)₃] with subordinate amounts of boehmite [AlO(OH)] (Clarke 1989). Moreover, unfired Chinese refractory bauxites contain greater amounts of alkalis and alkaline

earths than most other refractory-grade bauxite, resulting in high glass levels within the final calcined product (Table 10).

Currently, China has continued to expand the level of its calcined refractory bauxite exports and strengthen its market position to the degree that it has become the primary supplier of these high-alumina refractory raw materials to the world. In the early 1990s, some diversification of this restricted supply structure began to occur, with the development and expansion of export-oriented refractory bauxite production capacity in Brazil. Initially, the first inroads into world markets by Brazilian refractory bauxite were made at the expense of Guyanese product. That is because both Brazilian and Guyanese refractory-grade bauxite are principally gibbsitic ore, whereas Chinese bauxite is predominately composed of diasporic and diasporic kaolin. By the late 1990s, the Brazilians had captured approximately 13% of the market, compared with a 17% share for the Guyanese, while the Chinese maintained their dominance with an estimated 70% share of the world's refractory bauxite market (Russell 1999). After Brazil, China, and Guyana, other current sources of refractory-grade bauxite are relatively minor. Greece produces some material that has been used largely for domestic and European markets. India has limited production capacities that, until recently, have principally supplied only domestic markets. Production from Suriname, the third largest supplier to the U.S. market in the early 1980s, ceased in 1983. Recently, further restructuring of the world's refractory bauxite producers occurred with the announcement that MSL Minerais S.A., one of Brazil's larger refractory bauxite producers and a major supplier to European markets, closed its operations in November–December of 2003 (Taylor 2003e). This eventually may provide a new marketing opportunity for Guyana and a chance to regain some of its previously lost market share.

Guyana. In Guyana, the source of refractory-grade bauxite over time has been the state-owned Guyana Mining Enterprise Ltd. (Guymine), which was responsible for mining and treating bauxite ore for the Bauxite Industry Development Company Ltd. (Bidco), the government's sales and marketing organization. In 1992, Guyana began restructuring the administration of its bauxite mining industry in an attempt to cut losses and lift productivity in order to eventually privatize its bauxite interests. The reorganization resulted in the formation of two new mining companies responsible for managing the operations that had previously been under the authority of Guymine: Linden Mining Enterprise Ltd. (Linmine) and Berbice Mining Enterprise Ltd. (Bermine). Both Linmine and Bermine are currently under government financial control (Anon. 2002; Taylor 2003e).

As noted, from the late 1970s, a major portion of all bauxite mined in Guyana was used as feed to produce calcined refractory-grade bauxite (Lachmansingh and Nooten 1977). During the 1990s, this percentage dropped and metallurgical-grade bauxite production once again gained a greater share of the country's total bauxite output. This was because a metallurgical-grade bauxite mine opened at

Aroaima on the Berbice River in 1991 and its dried ore was exported for the production of smelter-grade alumina. Refractory-grade bauxite production has been predominantly derived from what are now Linmine's mining operations near Linden on the Demerara River and in limited amounts from the mining operations in the Berbice River area of the Kwakwani district, operated by Bermine. The operations at the Linden location, approximately 100 km south of the nation's capital, Georgetown, have historically provided the majority of Guyana's RASC production (Hinds 1983, 1984). In 2001, Linmine reportedly had the capacity to produce 600,000 tpy of crude ore for nonmetallurgical purposes, and its processing plant's capacity was rated at approximately 300,000 tpy (Crossley 2001). Nevertheless, in recent years, actual production has fallen well below these former output levels (Anon. 2001).

China. Coincident with the supply difficulties that developed within Guyana in the late 1970s, China was gradually able to gain a major point of entry into the world's refractory-grade bauxite markets (Coope 1981; Lebauer 1982; Holroyd and McCracken 1993). In the early 1990s, total Chinese production of refractory-grade bauxite was estimated at approximately 2 Mtpy, with more than 700,000–800,000 tpy exported to international markets (Wang and Liu 1993). Accurate estimates of production levels are complicated, as stated earlier, by the fact that commercial definitions of what is actually classified as bauxite differ between China and the rest of the world. Currently, China is estimated to produce approximately 4.5 Mtpy of refractory clays and bauxite, with exports totaling 1.0–1.2 Mtpy of refractory-grade bauxite (Crossley 2001). The significant level of production and the associated market share that these Chinese refractories have attained since the market squeeze of the late 1970s was accomplished by overcoming a variety of product supply and quality problems.

Unlike Guyana, where a single uniform refractory bauxite product is produced from a few principal sources of ore, Chinese refractory-grade material is produced from many sources throughout the country and this has resulted in a wide variety of calcined refractory-grade bauxite products (Table 9). Guizhou, Henan, Shandong, and Shanxi provinces are the main producing regions of the country and each has a diverse number of independent centers for the calcination of refractory materials (Wang and Liu 1993; Zhong 1993; Crossley 2001). In turn, each calcining operation may have a variety of raw material sources or mining areas from which to draw crude ore. Nonetheless, the two leading refractory-grade producers are Guizhou and Shanxi provinces, with Guizhou providing bauxite of both higher alkalinity and higher density (O'Driscoll 2001). Generally, refractory-grade bauxite from southern China has a higher alkali content than ore from the northern part of the country. Beyond the issue of feedstock quality and variability is the additional complication created by the nature and quality of the calcining processes employed to produce Chinese refractory products. Traditional rudimentary natural draft shaft kilns are apparently used to produce a major portion of the Chinese calcined refractory-grade bauxite. These systems by their very design do not readily provide consistent and reliable quality control for the production of high-quality products that meet strict market specifications. In other calcining operations, antiquated batch "beehive" or round-type kilns, which are even more unreliable, provide a portion of the production. The introduction of modern rotary-type calcining equipment greatly improved the production situation. These systems normally produce a uniform, well-burned bauxite that commands a price superior to that of shaft- and round-kiln products. Despite this improvement in equipment, not all the quality problems were solved, because inadequately designed and operated combustion systems on some of the rotary kilns reportedly caused marked fluctuations in burning

rates, with an associated variability produced in the bulk density of the final calcined product.

In essence, all of these factors led to a very complicated quality control and product reliability problem for the consumers of Chinese abrasive- and refractory-grade products. To overcome these issues, in the mid-to-late 1990s, various Western merchants and consumers created several China-based subsidiaries or joint venture companies and set up processing facilities to supply new and more reliable nonmetallurgical bauxite products to the international markets. Consequently, in recent years, great strides have been made at improving the quality and reliability of Chinese nonmetallurgical-grade bauxite products. It was estimated in early 2003 that rotary kilns produced approximately 15% of China's refractory-grade bauxite (Crossley 2003b). Currently, many of the former state-owned enterprises have been privatized, and the Chinese government's efforts to end calcining operations with poor environmental or safety records, especially shaft and round kilns, has significantly reduced the previous overcapacity of the Chinese refractory bauxite industry. The closing of the polluting kilns, along with the government terminating operations at several illegal and unsafe mines, has increased the price of raw bauxite and reduced overall supply.

Brazil. The expanded development of refractory-grade bauxite deposits in Brazil during the mid-to-late 1980s offered the opportunity for further diversification in the worldwide sources of raw materials available to refractory consumers, especially in the North American and European markets. MSL Minerais S.A., a subsidiary of the private Brazilian industrial group CAEMI Mineração e Metalurgia S.A., entered the international market in the early 1990s with material from its Caracuru bauxite mine in the Jari region of the Amazon River basin, northern Brazil (Dickson and Harben 1986; Clarke 1989). MSL managed this mining operation in the Almeirim district of Pará state from 1985 until the end of 2003. In 1989, a new and modern 200,000 tpy beneficiation plant came on line to upgrade the run-of-mine ore. This development was in turn followed by the start-up in July 1990 of MSL's first 60,000 tpy rotary kiln to produce calcined refractory-grade bauxite. This refractory-grade bauxite production facility was expanded in August 1994 with the addition of a second 60,000 tpy rotary-calcining unit (O'Driscoll 1995). With facility streamlining and both kilns in operation, MSL Minerais upped its production capacity to nearly 150,000 tpy of calcined bauxite. Until the operation's closure at the end of 2003, Europe remained MSL's principal export market, with the United States and Japan taking minor amounts of its product (Taylor 2003e).

United States. Although U.S. sources of bauxite for alumina refineries exist and are being worked, with mining occurring in Andersonville, Georgia (Crossley 2001), the volume of bauxite required by U.S. industry demands that the importation of foreign-derived material be employed to meet market need. This is a fact that was made very evident during shortfall in production from Guyana in the late 1970s and early 1980s. The domestically produced bauxite is, in actuality, a natural mixture of bauxite and bauxitic clay, with a low to intermediate total alumina content, for which U.S. refractory and chemical manufacturers have developed a wide variety of applications (Dickson 1982). It occurs as bauxite and bauxitic clay lenses and pockets developed within the kaolin deposits of the Alabama and Georgia coastal plain. These deposits are usually small and only contain a few tens of thousands of metric tons of ore in each pocket or lens. This ore contains abundant silica, but is generally low in iron and exceptionally low in alkalis (Table 9).

Demand

The refractory industry is neither buoyant nor growing, and worldwide consumption of refractory-grade bauxite is currently esti-

mated to be between 950,000 tpy and 1.1 Mtpy (Russell 1999; Crossley 2001).

Throughout the 1980s, 1990s, and into the early part of the twenty-first century, the total annual consumption of calcined refractory-grade bauxite in the United States by the refractories industry ranged from a high of 524,000 t in 1988 to a low of 115,000 t in 2002, reported on a dry equivalent weight basis by the USGS (Figure 5). This general gradual downward trend parallels the decline in U.S. primary metal production, most notably, U.S. steel production.

Calcined bauxite consumption in refractories fell from 460,000 t for 1981 to 286,000 t in the economic recession of 1982, but recovered strongly to total 524,000 t in 1988. Affected by an economic slowdown in the early 1990s, the U.S. consumption of calcined bauxite in refractories fell to 328,000 t in 1991, about 28% below the 1981 level of consumption. In 2002, the last year for which reported figures are presently available, the U.S. refractory industry consumption of calcined bauxite had fallen to 115,000 t, as noted, a recent all-time low.

Calcined refractory-grade bauxite has found wide application as a principal feedstock for the 60%–90% alumina content category of refractory shapes and specialty products (castables, plastics, and ramming mixes). This is largely because it is the lowest cost, high-alumina raw material that is readily available and in abundant supply in the world's industrial minerals markets. This usage by the refractories industry is closely tied to the production and consumption of primary metals—in particular, iron and steel. On a worldwide basis, it is estimated that the iron and steel industry consumes approximately 70% of all high-alumina refractories (Everts 1984; Ramsahoye 1991; Cole 2001).

Although the iron and steel industry remains the major market for refractory bauxite products, technological shifts over the last decade or more have resulted in the expanded use of higher performance specialty refractories, bringing about a marked decline in the consumption of refractories per ton of steel produced in the world. It has gone from 23–30 kg of refractories per ton of steel in 1970 to the current level of about 10 kg/t (Crossley 2001; Moore 2004). It is now noted, however, that this downward trend has apparently started to level off. These changes have occurred primarily because of the transition a way from traditional ingot casting methods of producing metal to a continuous casting means of steelmaking, with an accompanying increase in the employment of the basic oxygen furnace and the electric arc furnace within the ferrous metals industry. Although overall demand for refractories in general has been projected to decline, as unit consumption continues to fall within the iron and steel industry, the outlook for high-quality Bayer alumina-based refractories remains somewhat more optimistic (see Specialty-Grade Alumina section, this chapter). A preference has developed for higher performance refractories, such as high-alumina materials, and this has meant that these products have increased their market share over the more traditional lower alumina categories of refractories (fireclay, pyrophyllite [$\text{AlSi}_2\text{O}_5(\text{OH})$], etc.) (Benbow 1989; McMichael 1990).

The entire U.S. demand reportedly accounts for approximately 50% of the western world's refractory-grade bauxite consumption. In 1981, imported refractory-grade bauxite accounted for 65% of the refractory bauxite consumed in the United States. In 1987, imports had increased their market share to 84%. By 2002, imported refractory bauxite amounted to roughly 95% of U.S. refractory bauxite consumption.

† Excludes 75,496 calcined † purchased for the NDS.

Throughout the 1980s imports into the United States principally came from Guyana and China. As previously noted, shipments from Guyana have declined in recent years, while those from China have tended to increase and, currently, the Chinese shipments to the United States remain at higher levels than either Guyanese or Brazilian imports. In 1981, China accounted for 49% of U.S. calcined refractory-grade bauxite imports, Guyana 40%, and Suriname 11%. At the end of the decade, in 1990, China supplied 60% of these imports, Guyana provided 40%, and there were no imports from Suriname, where production of refractory bauxite ceased in 1983 (Dickson and Harben 1986). By 1994, China's share of U.S. calcined refractory-grade bauxite imports had risen to 85%, while Guyana's shipments fell to 14% and Brazil accounted for about 1% of the total. In 2002, China accounted for 88% of these imports, Guyana provided 7%, and Brazil supplied 5%.

Because refractory-grade bauxite plays a critical and strategic role in the economy of the United States, the U.S. government has maintained stocks of this raw material in the National Defense Stockpile (NDS) for use during times of international turmoil and possible supply or market disruption. At the close of the 2003 fiscal year, the Defense Logistics Agency (DLA), manager of the NDS, listed the calcined refractory-grade bauxite inventory as 42,400 metric calcined t (41,800 long calcined t). Under the new Department of Defense Annual Materials Plan (AMP), submitted to the U.S. Congress by the Defense National Stockpile Center, the DLA proposed the sale of up to 43,700 metric calcined t (43,000 long calcined t) of refractory-grade bauxite during the 2004 fiscal year (i.e., all of the current inventory). This or the remaining inventory, whichever is lower, is the maximum amount recommended for disposal during the fiscal year under the new AMP, and the actual level of sales will depend upon the prevailing market conditions. The sales are part of the continuing U.S. government effort, following the end of the Cold War, to eliminate the NDS program.

Prices

Calcined refractory-grade bauxite prices remained relatively stable during 2003, with only a slight increase in the prices of Chinese material imported into the United States in the latter half of the year. This developing trend of increasing Chinese prices continued throughout the first half of 2004. Approximate baseline international market prices for refractory-grade bauxite imported to U.S. markets from Brazil, China, and Guyana are published monthly by the trade journal *Industrial Minerals*. In mid-2004, the price range for bulk Brazilian refractory-grade bauxite was \$115–\$130/t, free on board (f.o.b.) Brazil. The price quotes for Chinese refractory-grade bauxite, minimum 87% Al_2O_3 , f.o.b. trimmed Chinese ports, were as follows: Shanxi, shaft lump, \$125–\$140/t; Shanxi, rotary lump, \$125–\$140/t; and Guizhou, rotary lump, \$110–\$120/t. The price range for Guyanese refractory-grade bauxite was \$160–\$170/t, f.o.b. barge U.S. Gulf Coast. Marketplace adjustments are regularly applied to these base prices, depending on grain size specifications, size of order, and fuel cost factors. Because Chinese bauxite accounts for such a large portion of the refractory-grade market, fluctuations in the pricing of Chinese material have a n immense effect in the entire industry. In 2003, bauxite exported from China was subject to a pay-as-you-go license fee of 230 Chinese yuan (\$27)/t (Crossley 2003b).

Abrasive Applications

Abrasives are materials used to smooth, roughen, polish, or clean surfaces, or simply to remove materials for the purpose of altering surface shape or dimensions. Abrasives generally achieve their objective through a rubbing action but also may work by impact.

Producing calcined abrasive-grade bauxite is equivalent to processing refractory-grade material, except it is calcined at lower temperatures. Some of this calcined bauxite is used directly as an inexpensive abrasive product, but by far the largest amount is used as the feedstock for the manufacture of brown fused alumina.

Fused aluminum oxide abrasive grain (artificial corundum) is produced by the electrofusion of either calcined bauxite or Bayer-process alumina (Figure 1). In both instances, fusion is accomplished in electric arc furnaces at temperatures in excess of 2,000°C, the only difference being the resulting end product. Calcined abrasive-grade bauxite provides the feedstock for the production of brown fused alumina (Figure 1). Brown fused alumina normally contains between 94% and 97% Al_2O_3 . Between 1.2 and 1.5 t of bauxite are required to produce 1 t of brown fused alumina (Crossley 2002a). Fusion of calcined, high-purity, Bayer-process alumina, on the other hand, produces white fused abrasive grain (Figure 1 and Specialty-Grade Alumina section). White fused alumina contains 99.5%–99.9% Al_2O_3 .

Abrasive-grade bauxite, the feedstock for brown fused alumina, is prepared from low-silica, low-alkali material that is calcined at temperatures of approximately 1,100°C. This is lower than the firing temperature normally used for refractory-grade bauxite but high enough to ensure that the calcined product does not readily reabsorb moisture to reform hydrated compounds. The calcined bauxite is then electrofused in the presence of ground coke and iron borings that aid the electromelting process and facilitate the removal of impurities by electromagnetic separation. The mix is usually calcined bauxite (80%), coke (5%), and iron borings (15%). Fusion takes place at temperatures above 2,000°C and usually requires 2,750–4,400 kW-hr of energy per metric ton of brown fused alumina. As indicated, the process requires the addition of special additives to the electric arc furnace to form a ferrosilicon slag that scavenges impurities. A source of carbon is needed to act as the reductant for the oxides of iron and silicon to form the slag, and coke is the preferred source. The iron content is adjusted by the addition of iron borings and the ferrosilicon usually contains about 16%–18% silicon. The magnetic susceptibility of ferrosilicon provides an efficient means of separating it and its associated impurities from the fused alumina product. This separation is achieved by passing the crushed artificial corundum through magnetic separators.

Both chemical and physical criteria are used to determine if a calcined bauxite meets the specifications required for the production of brown fused alumina. As in the case of refractory-grade bauxite, the most critical chemical components for abrasive-grade bauxite are alumina, silica, iron oxide, titania, alkalis, and moisture—as both free and chemically combined hydroxyl groups. To maximize the efficiency of the electrofusion process, the alumina content of bauxite used for abrasive applications should be as high as possible, and a minimum alumina content of 80% on a calcined basis is normally required for this application. Even though the mineralogy of the bauxite itself is not of major significance, gibbsitic bauxite generally comprises the major portion of the feedstock to this industry. Silica is the most significant impurity and very costly to remove. In general, the upper limit on the silica content in calcined abrasive-grade material is 5%. Unlike refractory-grade bauxite, the iron oxide content is not as critical, and it can even reduce the need for iron additives to promote ferrosilicon formation, provided that the iron oxide:silica ratio does not exceed 3:1, although it is reported that the optimum ratio for this grade is closer to a value of 2:1. Titania, which is invariably present in bauxite, ideally needs to be in the range from 2% to 4%. If the titania content is too low, the corundum crystal structure is affected and the toughness of the fused alumina grain is impaired. Alternatively, if

the titania content is above the 4% threshold level, it must be reduced to below 4% in the ferrosilicon phase, which is exceptionally costly. As with refractory-grade bauxite, low concentrations of alkalis are a requisite of abrasive-grade material in order to minimize the formation of a glass phase. This fact is of particular significance if the calcium oxide (CaO) content rises to more than 0.1%. The presence of moisture or chemically combined hydroxyl groups can be a potential hazard leading to the possible explosive generation of superheated steam. Therefore, the LOI of the calcined bauxite should not exceed 1%, and covered storage is commonly used for abrasive-grade products. Table 12 gives a comparison of the chemical composition of a variety of calcined abrasive-grade bauxites.

Besides these strict chemical specifications, a abrasive-grade bauxite also must meet certain physical standards. As previously mentioned, the calcined abrasive-grade feedstock should have been fired at temperatures high enough to ensure that the calcined material does not readily reabsorb moisture to reform hydrated compounds before it is fused in an electric arc furnace. Particle size is especially critical for abrasive production. The upper limit on particle size is 50 mm with the lower threshold set at a 100-mesh (0.150 mm) screen size. If the material is too coarse, complete calcination may not be achieved, and any material finer than 100 mesh is likely to create dusting problems, resulting in material losses during handling, transportation, and fusion.

Depending on the chemical composition of the bauxite feed, two main types of brown fused alumina are produced, regular and semifrable. The primary distinguishing factor is the amount of TiO₂ present, with the semifrable variety having the lower titania content (<2% TiO₂). In the production of the semifrable material, Bayer alumina is added to the process in order to reduce the levels of silicon and titanium impurities in the final brown fused alumina product (O'Driscoll 2003).

As indicated earlier, a significant portion of the world's current brown fused alumina production is used beyond the abrasive sector and a substantial amount finds use in refractory applications, as monolithics and shaped products (Figure 1). In the abrasives market, abrasive grain fused aluminas are used primarily in three basic ways: (1) loose form; (2) dispersed form glued to a flexible backing (coated abrasive product); and (3) bonded form comprising closely packed grains held together in a three-dimensional form by inorganic or organic bonds (bonded abrasive product). Coated and bonded products are the main abrasive markets for brown fused alumina.

Sources of Supply

The principal sources of abrasive-grade bauxite are Australia, China, Greece, Guyana, and Italy. Collectively, these countries supply the majority of the world's abrasive-grade bauxite. The world's production capacity for brown fused alumina is currently estimated at about 1 Mtpy (O'Driscoll 2001). Until 1987, Suriname was also an important supplier of abrasive-grade bauxite, especially to the United States, but has withdrawn from the market. Additionally, Guinea, an intermittent supplier of abrasive-grade bauxite, once again ceased production and dropped out of the market at the end of 2001 (Crossley 2002a). Over the last decade or so, as a result of aggressive product pricing, China has grown into the position of being a key supplier to the world's abrasive bauxite markets (Gasser 2002). China's existing production capacity for brown fused alumina is estimated at some 450,000–500,000 tpy. Reportedly, there are more than 60 producers, with most located in Guizhou and Henan provinces, but some are also located in Guangxi, Shanxi, and Sichuan. Current exports are on the order of 300,000 tpy, which have steadily risen since the mid-1990s (O'Driscoll 2001).

A possible new supplier to international markets may be India (Taylor 2003b). Although India currently imports 40%–60% of its calcined bauxite requirements from China, efforts have recently been made to market abrasive-grade material from the state of Gujarat to world markets. Nonetheless, a fundamental question still exists as to the quality and quantity of nonmetallurgical-grade bauxite that Indian sources will be eventually capable of supplying to export markets. It is noted that calcined nonmetallurgical-grade bauxite from India typically contains more iron, titania, and CaO than similar material from China and Guyana; however, the Indian bauxite is reported to be comparatively easier to grind (Crossley 2001).

Demand

Currently, worldwide demand for calcined abrasive-grade bauxite is estimated at approximately 800,000 tpy to 1 Mtpy (Russell 1999; Crossley 2001). Through the 1980s, 1990s, and into the twenty-first century, the total annual consumption of calcined abrasive-grade bauxite in the United States by the abrasives industry has ranged from a high of 328,000 t in 1984 to a low of 52,000 t in 2002, reported on a dry equivalent weight basis by the USGS (Figure 6).

Table 13 identifies foreign sources of calcined abrasive-grade bauxite destined for U.S. industrial users.

At this time, the overall consensus is that the future for bauxite-based abrasives is not particularly bright. It is a mature market that is

in broad decline, and demand for brown fused alumina in the abrasives sector has slowly declined but is now expected to remain static or drop at only a reduced rate in the future. In recent years, demand for abrasive-grade bauxite in North America and, to some extent, Europe, has decreased because of cheaper Chinese exports of brown fused alumina entering the international marketplace.

Prices

As with many industrial minerals, prices for abrasive-grade bauxite are difficult to trace because a huge amount depends on the precise chemical and physical specifications of the material. As a general tenet, abrasive-grade bauxite ores sell for around two-thirds the price of refractory-grade bauxite. The newsletter *Mineral Price-Watch* quoted the mid-2004 price range for abrasive-grade bauxite, f.o.b. China, as \$65–\$70/t (Anon. 2004b). Chinese abrasive-grade bauxite is typically the cheapest product available because it normally has a relatively high calcium oxide content.

Cement Applications

In terms of volume—metric tons of material used—cement applications have become the largest market for nonmetallurgical-grade bauxite. Two types of aluminous cement are produced directly from bauxite (low- and high-iron varieties; see Figure 1). Additionally, some bauxite is used to upgrade the alumina content of the raw materials used to produce ordinary portland cement.

In cement products, the higher the alumina content, the more rapid the hardening rate and the better the refractory properties. These factors have led to the added use of calcined alumina for the production of a special class of high-purity calcium aluminate cement (CAC). CAC is typically produced from high-purity limestone and calcined alumina in place of bauxite and contain 70%–80% Al_2O_3 , 18%–25% CaO , and less than 2% total silica, soda, magnesia (MgO), and iron oxide impurities. Normally, it is designated as high-grade CAC (>70% Al_2O_3).

High-Alumina Cement

Aluminous cement differs from standard portland cement, both in its chemical composition and its end uses. The raw materials employed to produce high-alumina cements are normally bauxite and limestone, whereas portland cement uses aluminous clay or shale rather than bauxite. As a consequence, high-alumina cement consists of calcium aluminates as opposed to aluminosilicates and it is often termed calcium aluminate cement. It is used principally in the castables sector of the monolithic refractories market. The calcium aluminate cements are commonly classified commercially by their alumina contents as low (CAC40), medium (CAC50), or high (CAC>70) grades, with color grading from dark gray to white. The low- and medium-grade varieties are derived from bauxite raw materials and are differentiated on their iron content, while the high-purity variety is only sourced from alumina feedstock. The most frequently used aluminous cements are in the 40%–50% Al_2O_3 range, which are described as the low-medium grade CAC, with the >70% CAC or higher purity grade CAC being used in lower volumes and more high-end applications. The typical range and associated differences in chemical compositions encountered within the low- and medium-grade calcium aluminate and portland cements are shown in Table 14. Please note that the high-purity calcium aluminate cements are not included in this table, only the low- and medium-alumina grades (CAC40 = high iron, CAC50 = low iron).

Concrete made with high-alumina cements is characterized by their rapid setting times, as short as 2–4 hours, with structural strength developed within 24 hours, as compared with conventional

portland cement-based concrete that may require several days to harden. In fact, the initial strength of CAC-based concrete after 1 day is proportionally the same as that for portland cement-based concrete after 28 days (MacZura 1992; O'Driscoll 2000).

Fundamentally, there are two principal types of high-alumina cement produced from bauxite feed: high and low iron, which are also termed low- (CAC40) and medium- (CAC50) grade calcium aluminate cements (Table 15). Both varieties can be used in castable refractories with operating temperatures up to 1,200°C. The high-iron type, often termed *Ciment Fondu*, when used in conjunction with a suitable aggregate such as a refractory grog, can be employed as a refractory cement and mortar that retains its integrity up to 1,300°C. These high-alumina cements are also resistant to chemical attack by corrosive agents (i.e., salt water, etc.).

Bauxites used in high-alumina or calcium aluminate cements range considerably in chemical composition. The primary chemical determinant affecting the selection of bauxite for use in high-alumina cement is the silica content, or, more precisely, the alumina-to-silica ratio. A high silica content hampers the rapid hardening property of the cement. This means the silica content must be controlled and a typical industry requirement is that the $\text{Al}_2\text{O}_3:\text{SiO}_2$ ratio should be at least 10:1, which normally excludes bauxite containing more than 6% SiO_2 from use in high-alumina cements. For the low-iron compositions, it is common to specify an iron oxide content of less than 2.5%, whereas for the high-iron grade (*Ciment Fondu*), contents of 25% may be acceptable in certain applications,

although the norm lies in the 10%–18% range (Table 14). Iron contributes to the hardening properties and acts as a flux, but if present in excessive amounts, it may have adverse effects on the cement's refractoriness and overall strength.

The two main methods employed to produce high-alumina cement are the fusion and sintering techniques. In the fusion process, an oil-fired, L-shaped vertical shaft/reverberatory hearth kiln is normally used to produce the high-alumina cement product, whereas a rotary kiln is used to fire the bauxite and limestone raw materials in the sintering process. The production method used often dictates the physical requirements of the bauxite feedstock chosen by a cement producer. In processes using rotary kilns, where the bauxite is ground and mixed with limestone before sintering, particle size of the crude bauxite is of minor importance. On the other hand, the fusion method for manufacturing high-iron Ciment Fondu involves charging a mixture of coarse, lumpy, monohydrate-type bauxite (boehmite or diaspore) with limestone into a combination vertical shaft/reverberatory furnace where rising volatiles from the fusion hearth preheat the descending feed. The molten furnace discharge is cast into pigs that are subsequently ground and size classified to cement fineness. This operation is dependent on coarse feed (50–100 mm) to prevent channeling of the hot gases in the shaft furnace. As indicated, boehmite or diaspore is normally selected because of their low LOI, which results in lower levels of disintegration and thereby presents less interference with gas flow through the furnace feed. Economic concerns provide yet another impetus for selecting monohydrates, because they customarily have free and chemically combined hydroxyl contents of 15%–17%, compared with the normal 35%–40% for gibbsitic bauxite (Table 1). This has an obvious impact on the fuel requirements plus materials handling and transportation costs incurred by cement manufacturers.

The alumina content of low-iron type, high-alumina cements normally ranges from 50%–57% Al_2O_3 , which is slightly above the levels found in the high-iron, Ciment Fondu types but well below the levels found in high-purity CAC (CAC70–80) produced directly from alumina feed stock. Silica also can be tolerated in quantities similar to that permitted in the high iron-grade material, and typically is in the 4%–6% range (Table 14). The most striking difference in chemical composition between the low- and high-iron grades is in their iron oxide content. The maximum acceptable amount of Fe_2O_3 allowed in the low-iron type may reach 3%, although it is actually more commonly maximized at 2.5%. This translates in to a minimum $\text{Al}_2\text{O}_3:\text{Fe}_2\text{O}_3$ ratio of 20:1. The titania content is also of significance for this material, with a minimum $\text{Al}_2\text{O}_3:\text{TiO}_2$ requirement of 16:1. Although the high-iron grade is usually produced in oil-fired vertical shaft/reverberatory hearth furnaces, the low-iron type is ordinarily produced in rotary kilns or in a few instances by fusion in electric arc furnaces (Andrews 1984; O'Driscoll 2000). In this latter case, a product similar to Ciment Fondu is produced though usually lower in iron content ($\text{Al}_2\text{O}_3:\text{Fe}_2\text{O}_3$ usually greater than 20:1) and a finer-sized bauxite feed can be used to manufacture this product, with optimum results obtained using calcined bauxite.

Portland Cement

This is the most frequently used binder in the commercial production of concrete. The essential raw materials for portland cement are limestone and high-alumina clay or shale. In some cases, the alumina content of the clay or shale feedstock is too low for the formation of the required mineral phases during sintering of the cement and, therefore, bauxite is used to upgrade the feed. One of the parameters typically used to determine the suitability of the raw materials for this application is the SiO_2 -to- $(\text{Al}_2\text{O}_3 + \text{Fe}_2\text{O}_3)$ ratio,

commonly known as the “silica modulus,” which in this case should ideally be in the range of 2.6–2.8 with the alumina content exceeding the iron oxide. The principal criterion for suitability is a high level of alumina content (Andrews 1984).

Beyond the use of bauxite to increase the alumina content within the raw materials employed to produce portland cement, there are several other compelling explanations why the cement industry has turned to bauxite as an additive in the manufacture of this product. By using low-silica bauxite, the industry is able to utilize low-grade, high-silica limestone that has previously been classified as subgrade material and in turn this has greatly increased the limestone reserves available for use as feed to the portland cement industry. Additionally, reduction in alkali content can be achieved by using a bauxite-based feed that in return permits a broader range of reactive aggregates to be incorporated into the final concrete mix. Besides these factors, other advantages include improved kiln control and increased product uniformity, improved materials handling, and a reduction in freight costs. Nevertheless, although chemically ideal for use in cement production, bauxite is usually prohibitively expensive and used only as an additive in portland cement, typically forming only 2%–3% of the raw mix, and not as a basic feedstock.

In addition to the previously mentioned cements, there are also two variants of portland cement, one known as blast furnace cement, which is derived from the aluminous slag produced as a coproduct of the iron industry, and the other based on fly ash wastes from coal power plants. The y are both significant competitors to bauxite's use as an additive to portland cement.

Demand

Worldwide use of bauxite in the cement industry is estimated at about 1.0–1.2 Mtpy (Russell 1999; Crossley 2001). This places the use of bauxite in cement at the top of the list of all nonmetallurgical markets, in terms of tonnage. The total global market for high-purity CAC is currently estimated to be 500,000–550,000 tpy, and is forecast to remain at these levels in the near future (Russell 1999; O'Driscoll 2004).

In 2001, the USGS started reporting the U.S. cement industry's annual consumption of bauxite, as reported on a dry equivalent unit basis. It was found that the cement industry consumed 268,000 t of bauxite in 2000, 302,000 t in 2001, and that the consumption level had risen to 324,000 t by the end of 2002. Although the markets for cement in Europe and North America are growing at moderate rates, demand is expected to substantially increase in Asia, especially in China, where consumption is expanding very rapidly in both the refractory and building materials markets.

Prices

There is a significant price differential between bauxite used for aluminous cement production and that for portland cement, with bauxite used in aluminous cement (55%–56% Al_2O_3) being at least double the price of bauxite for portland cement (Russell 1999). The difference is even greater between the high-end products, with CAC reportedly four or five times more expensive than portland cement (O'Driscoll 2000).

Chemical Applications

The bauxite used directly for chemical applications is very high quality material and, in some cases, is basically equivalent to crude or green gibbsitic refractory-grade bauxite that has not been calcined.

The most direct use of bauxite within the chemicals industry is in the production of aluminum sulfate [$\text{Al}_2(\text{SO}_4)_3$ or $\text{Al}_2(\text{SO}_4)_3 \cdot 18\text{H}_2\text{O}$], also commonly known or referred to as *alum*,

which is used principally as a flocculating agent in water and effluent treatment. This chemical application is derived from the fact that polyvalent ions such as Al^{+++} , and to a lesser degree Fe^{+++} , have the capacity to function as flocculating and coagulating agents. The tri valent aluminum ion is normally favored over the ferric species because of its greater flocculating capability and absence of color. Dissolving high-quality, specialty-grade bauxite in sulfuric acid (H_2SO_4) commonly produces this compound, and only certain types of bauxite are amenable to this acid treatment. The solubility of gibbsite in H_2SO_4 is significantly higher than that of boehmite and, therefore, gibbsitic bauxite is commonly used for this application. Diaspore is relatively insoluble in sulfuric acid, except at temperatures around 300°C . The kaolin that is often present in bauxite also dissolves at a rate comparable with gibbsite; in fact, kaolin also can be used as a feedstock to produce aluminum sulfate. A much purer chemical form of aluminum sulfate, free from iron contamination, is often produced by direct acid treatment of Bayer-process aluminum hydroxide (Figure 1 and Specialty-Grade Alumina section). This high-quality, colorless, iron-free product is specifically used as a sizing agent in the paper industry.

Some of the other principal chemicals that theoretically can be manufactured from bauxite are aluminum chloride (AlCl_3 or $\text{AlCl}_3 \cdot 6\text{H}_2\text{O}$), aluminum fluoride (AlF_3), and sodium aluminate, although the preferred feedstock for the higher purity forms of these chemicals is, once again, aluminum hydroxide derived from the Bayer process (Figure 1 and Specialty-Grade Alumina section). Treating heated bauxite with chlorine gas is a common method used to commercially produce aluminum chloride.

The most significant requirement for chemical-grade bauxite is that its acid-soluble iron oxide content should be low. Chemical manufacturers customarily specify a maximum Fe_2O_3 content of 2.0%–2.5%, or an $\text{Al}_2\text{O}_3:\text{Fe}_2\text{O}_3$ ratio of about 23:1 or higher. Nonetheless, this is not an extremely stringent specification and it is totally dependent on the ultimate end use of the material, because much greater iron oxide levels may be tolerated in some water and effluent treatment applications. Even less crucial is the silica content because silica separates out as an insoluble residue during the acid digestion process. Usually, silica levels of 10% and higher in the raw bauxite ore can be tolerated; however, toxic ions must be avoided and high levels of organic compounds adversely affect water quality (Andrews 1984; Benbow 1988). In practice, the U.S. chemical industry often utilizes bauxite with high silica contents for water treatment applications, even though these high silica levels substantially increase material handling costs.

Another special type of chemical-grade material is prepared by low-temperature roasting ($400^\circ\text{--}800^\circ\text{C}$) of low-iron gibbsitic bauxite. The resultant product is a residue of coarse, abrasion-resistant particles that retain only 4%–10% chemically combined hydroxyl groups. As this is a reversible process, the “activated” bauxite readily recombines or adsorbs moisture. This makes activated bauxite an excellent drying agent for gases and organic liquids. In fact, this partially dehydrated material is also known for its porosity and high surface area, which greatly contribute to its reactivity and enhance its use as an adsorbent for sulfur- and fluorine-based compounds. Activated bauxite is commonly used as a decolorizing and moisture removal agent for the food and chemical processing industries. However, activated bauxite’s use as a Claus catalyst for the removal of sulfur from sour gas in the petroleum industry has been mostly superseded by purer activated aluminas produced directly from Bayer-process aluminas (Figure 1 and Specialty-Grade Alumina section). Actually, in the late 1990s, it was reported that only one signif-

icant producer remained as a supplier of activated bauxite to world markets, the Porocel Corporation that produces both activated bauxite and alumina at its Little Rock, Arkansas, plant (Russell 1999).

Sources of Supply

The principal sources of chemical-grade bauxite are Brazil, Ghana, and Guyana. Currently, it is estimated that around 80% of the world’s chemical-grade bauxite produced each year is supplied by Guyana.

Demand

Currently, worldwide demand for chemical-grade bauxite is roughly estimated at about 300,000–350,000 tpy (Russell 1999; Crossley 2001). Through the 1980s and into the 1990s, the total annual consumption of chemical-grade bauxite in the United States for direct use within the chemical’s industry has ranged from a low of 169,000 t in 1982 to a high of 281,000 t in 1983 (Figure 7). In recent years, this information has been withheld by the U.S. government to avoid disclosing company proprietary data; nonetheless the general level of U.S. consumption through various economic cycles is readily evident in the available data.

The current global outlook for chemical-grade bauxite markets is generally downbeat or negative. Aluminum chemical production is a mature to declining market for bauxite. Increasingly, as noted, Bayer alumina has taken over from bauxite in the production of higher quality aluminum sulfate products. Furthermore, the entire market for alum itself is under great pressure because of technological advances occurring within its water treatment and papermaking applications.

Prices

Because of the high-alumina content of chemical-grade bauxite, it can command a premium price, but below that of refractory grade because no calcination cost is included in its production. Prices for chemical-grade bauxite are reportedly stable and estimated in the range from \$40/t to \$50/t f.o.b. for bulk shipments (Russell 1999).

Special Applications

Slag Adjuster

The iron and steel industries commonly use additives to control the viscosity of slags developed in metal production. There are two principal areas in ferrous metallurgy where bauxite may be used as a slag adjuster. The primary use is in iron making, where bauxite is added to control the desulfurization capacity and fluidity of the slag and which, at the same time, provides feed for the manufacture of blast furnace cement. In addition, raw bauxite is also used to control the viscosity of slags during the production of steel. In general, monohydrates (boehmite or diaspore) are favored for these applications. Worldwide consumption of bauxite in steelmaking is estimated to be in the range of 350,000–400,000 tpy (Benbow 1989; Russell 1999; Crossley 2001).

Most bauxite used as a flux in iron and steelmaking must be high in alumina content, usually greater than 55%, and low in silica content. The maximum tolerable SiO_2 content commonly is 7%. Only trace amounts of sulfur and phosphorus may be present in bauxite used in the iron and steel industry. Low moisture content, both free and chemically combined hydroxyl groups, is also desirable.

Bauxite supplied to pig iron producers as a slag adjuster is predicted to be a growth area for the specialty use sector; even so, demand is closely tied to the overall fortunes of the steel industry (Russell 1999).

Proppants

The specialty market products known as *proppants*, or *propping agents*, are associated with hydraulic fracturing, employed in the oil and gas industry to enable hydrocarbon recovery from deep petroleum reservoirs. In the hydraulic fracturing procedure, oil or gas held at great depths in tight rock formations is released by using high-pressure fluids to crack open the host strata. Grains of sand or other materials, known as proppants, are usually introduced into the fractures to keep them open and provide permeable structures through which the gas or oil may migrate and be collected by a recovery well. For shallow reservoirs, selected quartz sands with high natural sphericity and roundness are sufficient to resist the loading pressure of the overlying rock. At greater depths, in excess of 3,000 m, quartz proppants are unable to prevent fracture closure and sintered bauxite is chosen for this application (Crossley 2002a; Taylor 2003c). The general chemical specifications for bauxite used in the manufacture of proppants are high alumina content and low silica and clay content, with the associated iron oxide content not being critical. The bauxite is ground to a particle size of less than 12 μm and then agglomerated into very small spheres prior to being sintered at around 2,000°C. The sintering process forms randomly oriented alpha-alumina crystals that provide the material with its toughness and high-bearing strength. To provide a product with maximum permeability, the proppant is screened into a restricted range of particle sizes, extending from 6- to 80-mesh (3.35- to 0.18-mm) screen size. The most frequently used size is the 20- to 40-mesh (0.85- to 0.425-mm) range (Andrews 1984).

Demand for calcined bauxite in proppant applications is likely to increase in the future because of the hydrocarbon industry's increasing use of high-pressure fluid injection techniques to enhance deep and tight reservoir recoveries, plus the global trend toward greater production depths for both oil and gas.

Miscellaneous Minor Applications

In addition to the uses already described, there are some minor applications that require calcined bauxite as a primary feed stock. Although the principal applications of calcined bauxite remain in the refractory and abrasive industries, a few other very specialized commercial uses have been developed for this fired product, among which are welding flux materials and road surface aggregate. In total, these specialty end uses comprise a very small share of the entire nonmetallurgical-grade market.

Techniques for submerged arc welding require the use of a granular flux to shield the molten weld pool from the atmosphere during the weld's application or placement. Various proprietary compositions exist and in some cases calcined bauxite is incorporated into these formulations. Calcined bauxite may, in some instances, make up to 25% of the welding flux. In this special application, the most crucial specification involves the residual moisture content after calcination. It is mandatory that the moisture content should not exceed that allowed for calcined refractory-grade material (i.e., 0.5%). The reason for this rigorous requirement is the potential for any moisture present within the flux to reduce to hydrogen, if it is exposed to a welding arc. Should this occur, and if the molten weld pool absorbs the hydrogen, it will induce brittleness into the weld. Likewise, tight specifications also govern the presence of sulfur and phosphorus, which are detrimental to the weld. When present at high concentrations, they induce porosity and cracking, and at lower concentrations, they adversely affect the impact strength of the weld. Very few bauxite producers specifically sell welding-grade material, as the market for this product is rather small. Chinese producers are mostly located in Zunyi, Guizhou Province, southern China, and reportedly have a total annual output of 35,000 t. In the past, a Brazilian producer was also known to supply a few thousand metric tons to world markets. During the late

1990s, prices for welding-grade bauxite generally fluctuated in the \$85–\$100/t, f.o.b. China (Zhanjiang), range (Russell 1999).

Another very unique but, nevertheless, potentially significant market for calcined bauxite is as a special anti-skid road aggregate. This use was originally developed in the United Kingdom and has been tested for more than 20 years in that country. As this anti-skid material is the most expensive form of road aggregate, the calcined bauxite-epoxy resin mix is only used at the most crucial road locations to prevent accidents (i.e., road junctions, sharp corners, traffic lights, and pedestrian crossings in residential and urban areas). Even though this is currently only a small-volume usage, it is projected that its consumption will increase as markets are developed, particularly in Europe. This specific specialty application has seen only limited use in U.S. markets.

Specialty-Grade Alumina

A wide variety of high-quality abrasive, ceramic, chemical, and refractory products are produced directly from specialty-grade Bayer-process alumina and calcined alumina (Figure 1). As has been noted, these products and their associated markets require quality raw materials with greater alumina contents than can be provided by naturally occurring nonmetallurgical-grade bauxite. The difference between specialty-grade alumina and nonmetallurgical-grade bauxite as sources of supply to these very demanding markets is primarily one of product purity and cost. Methods of production, product specifications, and commercial markets have been addressed in broad and general terms in the preceding discussion of nonmetallurgical-grade bauxite products. Typically, Bayer-produced alumina is the starting point for most of the calcined alumina and alumina trihydrate used as feedstocks in these specialty alumina applications. Today, specialty-grade alumina plays an increasingly important role in the industrial minerals marketplace as the demand for superior products continues to grow. To take advantage of the higher prices offered for these materials, nearly all major alumina producers have converted a portion of their production capacity to the supply of specialty-grade alumina. Producing specialty-grade aluminum hydroxides, which differ in color, particle size, purity, and various other attributes from normal smelter-grade product, have required substantial capital investment in separate processing and handling facilities. Table 16 lists the key facilities that produce specialty- or nonmetallurgical-grade alumina products.

In 1975, alumina produced for nonmetal applications totaled 1.7 Mt, whereas in the late 1990s the worldwide total was estimated at closer to 5.1 Mt (Russell 1999). The International Aluminium Institute (2000) reported that world alumina production in 2002 totaled 56 Mt and approximately 8% of this (roughly 4.4 Mt) was alumina for nonmetallurgical uses. This may be a slight underestimate for the nonsmelter-grade alumina because some Bayer refineries do not typically differentiate between smelter- and nonsmelter-grade product in their total production figures. It is estimated that about 65% of the nonmetallurgical-grade alumina output is used directly to produce specialty Bayer alumina products; the remainder is processed into calcined specialty-grade alumina (Table 17).

Specialty-grade alumina is normally classified according to its soda (Na_2O) content, crystal size, specific surface area, and particle-size distribution. They are characteristics that influence the commercial applications for which these special products are finally used and the markets in which they compete.

The major specialty-grade products and their markets, listed in the general order of increased energy input requirements for product production, are described in the following sections.

Alumina Trihydrate

A prime workhorse or key feedstock for the specialty alumina market (Figure 1) is alumina trihydrate $[\text{Al}(\text{OH})_3]$, also referred to as aluminum hydroxide $[\text{Al}(\text{OH})_3]$, or less commonly known as hydrated alumina ($\text{Al}_2\text{O}_3 \cdot 3\text{H}_2\text{O}$), and often termed ATH by industry. It is used in hundreds of chemical, filler, flame retardant, pharmaceutical, pigment, water treatment, and zeolite applications. Furthermore, it is extremely important to note the great complexity of the alumina trihydrate sector and how, like bauxite, it may be produced in one country, refined or processed in another, and marketed in yet a third.

Alumina trihydrate is the principal high-quality feed for the manufacture of a very wide array of aluminum chemicals. Even though specialty-grade alumina and nonmetallurgical-grade bauxite are considered as the primary sources for a great number of aluminum-based chemicals, only a few are produced in significant commercial quantities (e.g., aluminum chloride, aluminum fluoride, aluminum sulfate, and sodium aluminate). Nevertheless, this results in a considerable tonnage of high-purity aluminum hydroxides with low soda, silica, and iron oxide contents used on an annual basis for the production of aluminum chemicals.

The key end use for anhydrous aluminum chloride is as a catalyst in organic reactions. It is one of the principal catalysts used in the alkylation of aromatic compounds, such as benzene, by alkyl halides (Friedel–Crafts reactions). Aluminum chloride is also used in the production of various cosmetics and pharmaceuticals and in the manufacture of titanium dioxide (TiO_2), which is used as a pigment for paints.

Treating specialty-grade alumina with gaseous hydrogen fluoride, liquid hydrofluoric acid, or fluosilicic acid (H_2SiF_6) produces aluminum fluoride. This product is mainly used as synthetic cryolite in the makeup of the molten bath ($\text{Na}_3\text{AlF}_6 \cdot \text{Al}_2\text{O}_3$) employed in the electrolytic reduction of smelter-grade alumina to a aluminum metal by the Hall–Héroult process. It is currently estimated that aluminum fluoride consumption in the production of primary aluminum metal varies from 10 to 30 kg/t depending on the smelter technology employed, with the worldwide average placed at about 20 kg/t (Roskill Information Services 1993; Russell 1999).

As previously noted, aluminum sulfate (alum) is employed primarily as a flocculating or coagulating agent in water and effluent treatment. In addition, commercial-grade aluminum sulfate is widely used in the manufacture of paper. In the current marketplace, there are basically three grades of aluminum sulfate: industrial, low-iron, and iron-free alum.

Sodium aluminate is used principally for the production of synthetic zeolites used in the manufacture of detergents. The most important commercial form is termed zeolite A $\{\text{Na}_{12}[(\text{AlO}_2)_{12}(\text{SiO}_2)_{12}] \cdot 27\text{H}_2\text{O}$ or $\text{Na}_2\text{O} \cdot \text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2 \cdot 4.5\text{H}_2\text{O}\}$, used as a nonphosphate detergent builder that enhances or maintains the cleaning efficiency of the surfactant by controlling water hardness. Since the late 1960s, because of environmental concerns about the ill effects of waste phosphates in natural water systems, governmental legislation restricting or banning the use of phosphates in detergents has boosted the worldwide demand for zeolite A to nearly 1 Mtpy (Russell 1999).

Beyond these wide-ranging applications in the chemical industry, aluminum trihydrate also plays an all-important role as an additive and filler for paint, paper, plastic, and polymer products—most significantly in the field of flame retardants.

Specialty-grade alumina from the Bayer process is an inorganic mineral product that has a large number of the attributes needed to make it an effective and competitive contender in the commercial

Table 16. Principal plants producing specialty-grade alumina products (2003)*

Region and Country	Company	Location	Estimated Total Year-End Specialty-Grade Alumina Capacity, ktpy [†]	Product
North America				
Canada	Alcan	Brockville, Ontario	18	Activated alumina
	Alcan	Vaudreuil, Quebec (Jonquière, Quebec)	142	Specialty hydrate, dry hydrate, specialty calcined aluminas
United States	Alcoa	Point Comfort, Texas	220	Dry hydrate, calcined alumina
	Almatis	Bauxite, Arkansas		Specialty hydrate, reactive alumina, tabular alumina, cement
	Almatis	Dalton, Georgia		Filler, ground alumina hydrate
	Almatis	Leetsdale, Pennsylvania		Calcined and tabular alumina
	Almatis	Port Allen, Louisiana		Activated alumina
	Almatis	Vidalia, Louisiana		Activated alumina, catalysts, absorbents
	Aluchem	Cincinnati, Ohio	25	Secondary production of hard-burned calcined alumina
	Aluchem	Jackson, Ohio	25	Secondary production of intermediate calcined alumina and reactive alumina
	Sherwin Alumina—BPU Reynolds Inc.	Corpus Christi, Texas	300	Wet and dry hydrate, calcined alumina, chemical-grade alumina
	Kaiser Aluminum & Chemical Corp.	Gramercy, Louisiana	200–300	Chemical-grade alumina, flame retardants
	Ormet Corp.	Burnside, Louisiana	6 [‡]	Wet and dry hydrate, chemical-grade alumina
	Porocel Corp.	Little Rock, Arkansas	23	Activated alumina
	UOP L.L.C.	Baton Rouge, Louisiana	22.5	Activated alumina
South America				
Brazil	Alcan	Saramenha, Minas Gerais	10	Specialty alumina
	Alcoa	Poços De Caldas, Minas Gerais	125	Hydrated alumina, calcined alumina
Europe				
Bosnia and Herzegovina	Energoinvest	Birac, Vlasenica	40 (Closed because of civil conflict)	Some chemical-grade alumina
France	Alutech Aluminas (Pechiney)	Gardanne	135	Wet, dry, and ground hydrate, calcined, and very low soda aluminas
Germany	Almatis	Ludwigshafen		Tabular alumina, calcined specialty alumina, spinel
	Aluminium-Oxid Stade GmbH (Hydro Aluminium/Dadco)	Stade	410	Chemical-grade alumina
	Martinswerk GmbH (Albemarle Corp.)	Bergheim	350	Calcined specialty alumina, activated alumina, specialty hydrate
	Nabaltec GmbH	Schwandorf	80 (Bayer plant closed in 1994)	Secondary production of filler and calcined alumina for ceramic and refractory products
Greece	Aluminium de Grece, S.A. (Alutech-Pechiney)	Beotia, Distomon		Small amount of hydrated alumina
Hungary	Ajkai Alumina (Magyar Aluminium—MAL)	Ajka	230	Calcined specialty alumina, specialty hydrate
	Motim Co. Ltd.	Mosonmagyaróvár	80	Calcined specialty alumina, fused alumina
Netherlands	Almatis	Rotterdam		Tabular alumina and calcium aluminate cement (50 ktpy of calcium aluminate cement capacity)
Romania	Oradea Alumina Enterprise	Oradea, Bihor	20 (Plant closed in 2001)	Tabular, hydrate, and specialty aluminas
Russia	Boxitogorsky Glinozem	Boksitogorsk	200	Calcined specialty alumina, specialty hydrate, white fused alumina (110 ktpy of white fused alumina capacity)
Serbia and Montenegro	Aluminijuma Podgorica	Podgorica, Montenegro	140	Chemical-grade alumina
Slovakia	ZSNP	Ziar-nad-Hronom	100 (Plant closed for reconstruction)	Some chemical-grade alumina
Slovenia	Silkem d.o.o. (MAL/Talum)	Kidricevo	66	Specialty alumina—Tabular and ground aluminas, plus zeolites

filler market. These include a white or near-white color, large volume production base ensuring dependable supply, consistency of chemical and physical properties, availability in a broad range of particle-size distributions, chemical inertness, nontoxicity, and, ultimately, cost-effectiveness. Furthermore, alumina trihydrate's widespread use as a filler is directly related to its fire-retardant and smoke-suppressant properties (Sleppy et al. 1991). The use of alumina trihydrate as a flame-retardant filler in plastics and rubber has developed into a major market for this specialty product. The majority of this alumina trihydrate filler feedstock is used in plastic applications, but a substantial quantity is also used in rubber, particularly for carpet backing applications. In the early 1970s, the demand in this market increased significantly as a result of U.S. legislation designed to restrict the flammability of carpeting materials.

Basically, there are two principal types of fire retardant alumina trihydrate: those produced directly from Bayer-process hydrate by milling and products made by dissolving and re-precipitating Bayer alumina. They are typically referred to as milled and precipitated products. The precipitated grades usually achieve higher prices, profitability, and growth rates than the standard milled products (Rothon 2004).

All flame or fire retardants succeed by disrupting one or more stages of the normal combustion process. In the case of alumina trihydrate, it operates principally in the initial stages of the combustion process: heating and decomposition. Aluminum hydroxide decomposes at above 200°C to give alumina and water vapor. This reaction is strongly endothermic, resulting in the absorption of about 280 calories per gram of aluminum hydroxide. The maximum decomposition rate for aluminum hydroxide occurs between 300°C and 350°C, which roughly corresponds to the range of decomposition temperatures for the most commonly used commercial polymers. Therefore, when a polymer containing alumina trihydrate is heated, the aluminum hydroxide decomposes endothermally, acts as a heat sink, and slows the rate of temperature rise, and the rate of decomposition of the polymer. Additionally, the water vapor given off also serves to dilute any combustible gases generated and acts as a vapor barrier preventing oxygen from reaching the flame, thereby impeding the progression of a fire (Sleppy et al. 1991).

The added smoke-inhibiting capacity of alumina trihydrate fillers is largely attributed to the development of solid-phase charring during the combustion process, instead of soot formation. Moreover, smoke suppression is also probably partly related to the resulting endothermic dehydration of the burning material.

In the early 1990s, it was reported that alumina trihydrate held 45%–50% by volume of the entire flame-retardant market (Schmitt 1993). Annual worldwide consumption for this application is currently estimated to be approximately 400,000 tpy.

Alumina trihydrate suitable for use as a functional filler, extender, or pigment in paper and paint products must meet very strict color and brightness specifications. This is also especially true for specialty filler applications such as alumina trihydrate's use in the manufacture of synthetic marble (onyx), where whiteness is a critical element. The aluminum hydroxide produced by the Bayer process is normally an off-white color because of organic impurities originating from the bauxite ore and present in the caustic liquor, which impart a yellowish color to the hydroxide product. Therefore, special purification techniques are necessary to satisfy the coating and filler market demand for white hydroxide products. These methods include reprocessing the Bayer refining plant hydroxide by further dissolution in caustic and high-temperature treatment (liquor burning) of the Bayer-process liquor to destroy organic impurities and, thereby, whiten the final product (Sleppy et al. 1991).

Other specialty applications for alumina trihydrate include use in the pharmaceutical industry for dental hygiene products such as toothpaste, the manufacture of antiperspirants, and use in stomach antacid products.

Specialty alumina trihydrate, particularly fine, high-whiteness grades, command a noteworthy premium on price over smelter-grade alumina, and are also less susceptible to market volatility. The prices quoted in 2002 for some of these specialty materials were as follows: \$400/t for ground alumina trihydrate, \$700/t for superfine alumina trihydrate, and up to \$1,400/t for coated grades. This compared with \$400/t for calcined alumina and \$500–\$600/t for ground calcined alumina (Crossley 2002b).

Activated Alumina

This category of specialty alumina is produced from dry alumina trihydrate by partial calcination or low-temperature roasting to remove the majority, but not all, of its chemically combined hydroxyl groups. This partial dehydration process is typically carried out at temperatures in the range of 250°–900°C, under strictly controlled circumstances, so that only 4%–10% of the chemically bonded hydroxyl groups in the feed are retained in the final commercial

product. As with activated bauxite, this is a reversible process and it provides an activated alumina that readily adsorbs moisture.

Activated aluminas are employed as desiccants, catalysts, and catalyst supports (Figure 1). The higher purity of activated specialty-alumina products has enabled them to largely replace activated bauxite in many applications and launch a variety of new markets of their own. An actual example of this changing market structure is the case where activated alumina has essentially taken over from bauxite in the Claus catalyst market. The Claus process is principally used to recover sulfur in industrial processing operations where significant amounts of hydrogen sulfide are released (petroleum refineries, natural gas plants, and steel mills). In the early 1970s, activated bauxite was the exclusive Claus catalyst used for sulfur recovery, but by the mid-1970s, activated alumina had become a much more important player. This was driven by a broad industry effort to raise the level of catalyst effectiveness to meet increasingly more stringent air pollution standards.

In the catalyst support sector, activated and calcined aluminas are employed to support a number of catalysts in various applications, mainly in the petroleum refining industry. Moreover, one of the most important uses of alumina as a catalyst support is in the field of catalytic converters for pollution control on automobiles.

Activated alumina products are usually sold as granules or ball shapes, although some are also produced as powder.

The total annual worldwide market for activated alumina has grown rapidly during the last 10 years and is currently estimated to be on the order of 90,000–150,000 tpy (Pearson 1999; Russell 1999).

Calcined Alumina

The other major workhorse or chief feedstock in the area of specialty applications is calcined alumina, which is the primary raw material for numerous high-quality end uses in the abrasives, ceramics, and refractories industries (Figure 1). Beyond the significant role it plays on its own in these various specialty applications, it is also the primary feedstock for the preparation of sintered and fused aluminas that include such high-end products as tabular alumina and white fused alumina. Tabular or sintered alumina is mostly used in high-performance refractory materials, whereas white fused alumina is mainly used for grinding abrasives and in some refractory applications (MacZura 1992).

Basically there are three categories of calcined alumina, which are based on the soda (Na_2O) content and total amount of impurities in the final product. The two most common types are normal- and low-soda calcined alumina, produced by firing Bayer-process alumina, while the third is high-purity calcined alumina, with an alumina content higher than 99.9%. A portion of this latter category consists of ultra-high-purity alumina, with a 99.99% Al_2O_3 content, produced by the decomposition of aluminum-based salts, and thereby not directly derived from Bayer-process products (Russell 1999).

Normal-grade calcined aluminas have a soda content higher than 0.1% and generally less than 0.3%, with a total alumina content of 99.0%–99.5%. Low-soda calcined aluminas, on the other hand, occasionally referred to as thermally reactive aluminas, have an Al_2O_3 content of 99.7% and contain less than 0.1% Na_2O .

The critical economic considerations associated with the processing and producing calcined specialty aluminas are generally the same as those that were discussed for calcined non-metallurgical-grade bauxite products (i.e., fuel costs, economy-of-scale issues, etc.). As previously stated, the calcination process is a very energy-intensive industrial procedure. In the case of calcined alumina, the conversion to alpha alumina occurs at about 1,100°–1,450°C. As with bauxite, the traditional means of calcining specialty-grade alumina is in standard rotary kilns, with typical production rates of

50–350 tpd. Newer fluid-flash or stationary calciners have been developed, however, to replace rotary kilns in the production of all but the higher purity-grade alumina calcines. Flash calciners have a much greater production capacity, up to 1,550 tpd, lower energy use (30%–40% fuel savings), lower capital and maintenance costs, plus lower workforce requirements. They are an excellent fit for Bayer refinery plants producing large volumes of smelter-grade alumina for metal production. Nonetheless, few specialty-calcined products have the volume of commercial applications in their niche markets required to justify the high production capacity of fluid-flash calciners (Sleppy et al. 1991).

The refractory industry is by far the most significant market for calcined specialty alumina; it comprises an estimated 60% of the total production. Calcined alumina is used extensively in the production of high-purity calcium aluminate cement (CA C70–80), which finds wide use as cements, concretes, and mortars in refractory applications and as binders in monolithic formulations, particularly gunning mixes and castables (Russell 1999; O'Driscoll 2000). Additionally, this sector also consumes a major tonnage of tabular alumina that is made directly from calcined alumina feed. Low-soda calcined alumina is used extensively within the ceramics industry for applications in whiteware, porcelain and electrical insulators, tiles, and newly developed high-technology uses such as integrated circuit substrates and bioceramics. The ceramics account for approximately 25% of the calcined alumina market. The key properties that alumina imparts to a ceramic product are high wear resistance, corrosion resistance, excellent electrical insulation, high mechanical strength, and good thermal conductivity (Roskill Information Services 1993). In the abrasives industry, calcined specialty alumina is used in two principal sectors. The previously mentioned and largest volume use is as the primary feedstock for the production of white fused alumina. The other major application is for polishing and lapping compounds.

In the late 1990s, worldwide production capacity for all grades of calcined alumina was estimated at 1.15 Mt of product. This figure could even be placed as high as 2 Mt, if the calcined specialty alumina used to produce white fused and tabular alumina, plus spinel-based refractories, were included in the estimate (Russell 1999; O'Driscoll 2003).

Sintered Alumina

As noted earlier, calcined specialty-alumina feed is used to manufacture tabular alumina, a thermally stable form of alpha alumina (α - Al_2O_3). Tabular alumina is a high-density, high-strength form of α - Al_2O_3 produced by sintering agglomerated shapes of ground calcined alumina at 1,800°–1,900°C in shaft or rotary kilns. At these elevated temperatures, the alpha alumina recrystallizes to form large, elongated, tablet-like corundum crystals from which tabular alumina receives its name. Occasionally in the sintering process temperatures approaching 2,050°C, the fusion point of alumina, are used for some special products. In the firing process, however, other factors such as residence time of the feedstock may significantly influence the development and ultimate size of the tablet-shaped alpha-alumina crystals and, in some special instances, sintering aids such as MgO or SiO_2 may be added to the kiln feed (Russell 1999; Taylor 2003d).

These hard-burned (sintered) calcined alumina have good resistance to thermal shock and physical erosion, so they are principally used as raw materials for high-performance refractory materials (Figure 1). In fact, the largest consumer of tabular alumina is the refractories industry, which reportedly accounts for about 95% of the product demand (Russell 1999; Taylor 2003d). One of its most important applications is its use in blast furnaces and steel mills for

the handling of molten metal in the production of steel. Smaller end markets include abrasives, electrical insulators, and catalyst carriers.

The total worldwide market for tabular alumina is currently estimated at 270,000–300,000 tpy. Nevertheless, at present, the global supply of tabular alumina exceeds demand, and this oversupply situation is likely to continue in the near future. Significant short-term growth is not expected, owing to an increase in competition from low-cost alternative raw materials across the entire refractories market, as tabular alumina finds itself in direct competition with white fused alumina, brown fused alumina, and other specialty fused or sintered materials for this ever-tightening market.

In mid-2003, average selling prices for tabular alumina were reported around \$800/t, with considerable variation depending on the specifications and volumes sold (Taylor 2003d).

Fused Alumina

This category of specialty alumina is used primarily as a feedstock to the abrasives and refractories industries because of fused alumina's extreme hardness and high melting point. There are a variety of fused aluminas, however; the two most common types are brown and white fused, with brown being the most widely manufactured type. As already observed, brown fused alumina is produced from calcined nonmetallurgical bauxite, while the higher purity white fused alumina is manufactured directly from calcined specialty-grade alumina with a minimum 99.5% Al_2O_3 content (Figure 1). The feed for this application should also have a coarse particle size and a low soda (Na_2O) content. Pink and ruby fused aluminas are also derived from this same calcined specialty-alumina raw material. The overall toughness of the white fused product is increased by adding up to 2% chromium oxide (Cr_2O_3), which produces a pink, red, or ruby fused alumina product. These latter grades are used entirely for grinding wheel applications (O'Driscoll 2003).

Like brown fused alumina, white fused alumina is produced in electric arc furnaces at temperatures above 2,000°C. White fused alumina contains 99.5%–99.9% Al_2O_3 , and, after fusion, is crushed and ground, magnetically separated, and often acid washed.

There are three basic categories of white fused alumina, which are defined by their soda content: regular (0.4% Na_2O), medium (0.05% Na_2O), and low (0.018% Na_2O). In addition, another critical parameter is the crystal size of the product (Russell 1999; O'Driscoll 2003).

The high-energy inputs required for the production of fused aluminas have determined that these production facilities should be sited in areas producing abundant supplies of low-cost electricity, such as regions with plentiful sources of hydroelectric power.

White fused alumina is used mainly for grinding abrasives but also in the refractory industry, where it is often employed when dense refractories requiring high purity at high temperatures are needed, with the regular and medium soda grades most widely used in these applications.

In mid-September 2003, white fused alumina prices were quoted at \$530/t, f.o.b. China, and were on the rise because of increasing calcined alumina costs (O'Driscoll 2003). In comparison, at the same time, prices for Chinese brown fused alumina (lump <40 mm, f.o.b. China) were \$200–\$220/t (O'Driscoll 2003). White fused alumina abrasive grain is traditionally more expensive than its fellow fused product, brown fused alumina.

Transportation

The aluminum industry derives its supply of bauxite and alumina raw materials from mines and Bayer refineries that are spread throughout the world. Thus the industry developed the adage, "What is bauxite? It is red and comes in ships." On a more serious note, ocean freight

charges and other transportation costs can be very high in relation to the actual overall value of the basic metallurgical-grade raw material used by the industry. Consequently, the economics of transporting and handling these bulk materials are extremely important factors in determining expansions of production and siting new alumina refineries and smelters for the production of aluminum. The potential for obtaining substantial savings on raw materials shipping costs is a major part of the logic behind locating Bayer alumina refineries at or near bauxite mines. As noted earlier, on average it takes roughly 2 to 3 t of bauxite to produce 1 t of alumina, which has significant implications for the volume of materials shipped through the aluminum production cycle. The same general type of transportation and handling cost issues are also at play when the choice is made by a particular nonmetallurgical bauxite producer to supply a specific sector of the industrial minerals market. In the case of the nonmetallurgical-grade trade, higher value products are usually involved that are shipped in smaller tonnages or lots. In fact, these smaller tonnages may even be "piggybacked" with other industrial mineral bulk cargoes for shipment to market. Because of the great international distances between the source of supply and markets, shipping and handling charges are a sizeable component of the entire industry's total raw materials budget, and transportation efficiency is essential to achieving and maintaining industry profitability.

Because of its low cost, water transport via ship and barge is the preferred, if not the only viable, means employed for moving bauxite-alumina bulk cargoes throughout the world. Over the years, major improvements in the operating efficiencies and shipping infrastructure for exporting the seabulk commodities have been achieved by expanding stockpiling facilities, using faster shiploading equipment, dredging and deepening ports, and employing larger bulk cargo ships. In cases of ocean shipping, transportation costs typically diminish with increasing carrier size and shipping distance. Large carriers, such as the 65,000 dead-weight-tonnage Panamax class, have been found to be the most cost efficient oceangoing vessels for the metallurgical-grade bauxite-smelter-grade alumina cargo trade (Drewry Business Publications 1993). Typical shipping times for nonmetallurgical-grade bauxite to European markets is 6–8 weeks from China and 2–3 weeks from South America, which are in addition to the lead times required to produce the product and move it to port facilities.

In North America and parts of Europe, the use of railroad transportation is typically limited to short-distance haulage because of its normally higher costs. Rail transport is used extensively in China and some African countries, however, for the movement of bauxite ores from mines to processing facilities or ports for export shipment. In other countries, various combinations of both truck and rail transport are used to move bauxite overland to processing plants or markets.

ENVIRONMENTAL CONSIDERATIONS

During the last 25 years, bauxite mining and processing operations have made significant strides in addressing the environmental impacts of their industry. The principal areas of possible adverse environmental impact for both metallurgical- and nonmetallurgical-grade bauxite operations are located at the mines, bauxite beneficiation/processing plants, and Bayer alumina plants.

In 1991, a worldwide survey of 18 metallurgical-grade bauxite mining operations determined that the area mined at these reporting sites ranged from roughly 2 ha to 450 ha, with the average being 76 ha. The total number of hectares per year directly impacted by the mining operations amounted to 1,368 ha (Martyn 1992). The 18 mining locations used in the survey represented 65% of total world bauxite production at the time.

The International Aluminium Institute (2000) conducted a second survey in 1998 covering 27 mining locations representing 72% of the world total bauxite production. The survey found that metallurgical-grade bauxite mining occurs in four major climate groups, and the 1998 distribution was Tropical 48%, Mediterranean 39%, Subtropical 13%, and Temperate 0.5%. The vegetation types impacted by the bauxite mining operations were mainly forests (76%), followed by agriculture and pasturelands (19%) and shrublands (2%). Postmining land use was determined by this second survey to be 70% returned to native forest; 17% to pastureland and agriculture; 7% used for urban and industrial development, housing, and recreational purposes; and 3% to commercial forest. The total area mined per year in 1998 was reported as 1,591 ha, 80% of which was identified as wildlife habitat, and 11% (175 ha) of which was tropical rainforest. The earlier and smaller 1991 survey placed the yearly worldwide total area mined for metallurgical-grade bauxite at 1,368 ha. In 1998, 577 ha of mined area was identified as possessing important fauna species; of these, 527 ha or 91% was to be restored to wildlife habitat by planting of suitable vegetation. It was also reported that the companies responsible for producing 60% of the world's metallurgical-grade bauxite had established their own plant nurseries for the purposes of reforestation and revegetation. In 1998, reclamation plans were in place at 90% of the surveyed mines, compared to 55% in 1991, and the existing reclamation rate was found to be 1,256 ha/year.

The higher value of most nonmetallurgical bauxite, as compared to metallurgical-grade material, usually makes it economically viable for these open-pit operations to be developed to greater depths, so it is often necessary to dispose of larger quantities of overburden. In low-lying swampy areas where there is abundant groundwater, artificial lakes are sometimes constructed and the overburden removed by suction dredge. This has been the case for several mines in Suriname. These lakes or ponded areas must be carefully constructed to avoid large-scale destruction of the native tropical forest. Consequently, owing to circumstances such as these, well-designed mine reclamation programs must be established to ensure that these affected sites are rehabilitated to meet acceptable standards when mining operations cease. This often means replacing topsoil and reforesting the mined areas. In many parts of the world, this is achieved by setting aside and preserving topsoil stripped from active mining sites for later use on reclaimed areas.

Monitoring and controlling the environmental effects of bauxite mining and ore processing operations are continuing responsibilities and generally include monitoring programs for the following parameters: air quality, dust levels, groundwater quality, and liquid effluents. Consideration also must be given to the fauna, flora, and local human inhabitants near these various operations. At the processing site where bauxite is beneficiated by crushing and washing, proper sedimentation facilities are necessary, so that process water can be reused and the tailings may be properly disposed of. The drying and calcining facilities also need to be fitted with dust precipitators to protect air quality and prevent a high level of dust from leaving the plant's stacks. In the production of aluminum chemicals from bauxite, the proper disposal of acidic residue poses an environmental concern at some locations.

A major issue for the alumina and bauxite industry is the disposal of the massive amounts of red and brown mud residues generated from alumina production. The industry has held two major international meetings to address this issue, the first in Kingston, Jamaica, in 1986 and the second in Perth, Australia, in 1992. At the Perth meeting, it was estimated that the world's alumina plants were then producing more than 66 dry Mtpy of bauxite tailings or red mud residues. Depending on the quality of the bauxite and the

technical design of the Bayer plant, between 1.1 and 6.2 t of red mud are generated for each metric ton of alumina produced (Hausberg et al. 2000). This red mud waste stream contains insoluble sodium aluminosilicates, Fe_2O_3 , TiO_2 , and trace amounts of other oxides of metals such as nickel, vanadium, and zinc. The following listing gives some idea of the extremely wide range of chemical composition found in red mud residues from different bauxites: Fe_2O_3 , 30%–60%; SiO_2 , 3%–50%; Al_2O_3 , 10%–20%; Na_2O , 2%–10%; CaO , 2%–8%; and TiO_2 , trace–10%. Apart from the alkalinity imparted by the Bayer caustic leach solution, the waste stream residue is chemically stable and nontoxic (International Aluminium Institute 2000).

Significant research has been devoted to developing methods of drying, handling, treating, and designing storage and containment areas for red mud wastes, plus rehabilitation of the waste ponds. In addition, extensive effort has also focused on developing economic alternative uses for this current waste product. These have included, among many others, the possible use as an agricultural soil conditioner, in ceramics for the manufacture of brick and tile, in water treatment to filter wastewater effluent, in plastics as a filler material, and as iron oxide-based pigments for use in the cement and construction materials industries. To date, efforts have not been highly successful in finding or developing a large-scale, economically workable end use for the alumina industry's red mud wastes.

OUTLOOK AND FUTURE TRENDS

The principal end uses of nonmetallurgical-grade bauxite are directly related to the production and consumption of raw materials for basic heavy industry, such as primary metals, cement, chemicals, ceramics, and so forth (Wright 1990). This serves to make the demand for specialty-grade bauxite cyclical, as it is directly tied to the basic movements of heavy industry—the “smokestack” component of the world economy—a trend that is expected to continue well into the future. An additional concern facing producers of nonmetallurgical-grade bauxite is that most of these markets are mature and neither new nor likely to expand in the foreseeable future.

In the case of refractories, the highest value market for nonmetallurgical bauxite, the outlook for possible future growth lies in the development of more advanced refractories with increased product longevity or greater endurance within very harsh, high-temperature environments (Jain 1994). More sophisticated and demanding applications are being developed throughout the world for refractories, via the modernization of primary metal production processes (iron, copper, etc.), and this driving force will continue to stimulate demand for high-quality calcined bauxite products in the future (Fisher et al. 1993; Moore 2004).

As with all industrial minerals, an intense and persistent competition for markets exists throughout the entire spectrum of nonmetal applications for bauxite. This situation will continue and intensify over time as more sophisticated applications are developed for alumina-based materials. For the top-end and high-quality markets, nonmetallurgical bauxite will remain under sharp market pressure from Bayer-process aluminas.

Relatively new major suppliers of nonmetallurgical bauxite to the world market, such as Brazil and India, will continue to help diversify the sources of world supply and ensure the existence of a stable, long-term raw material resource base for the rest of this century.

A major restructuring and consolidation of the entire aluminum industry occurred toward the end of the twentieth century and start of the twenty-first century, leaving only two or three major integrated world producers, principally Alcoa and Alcan. This has

had and will continue to have only a slight impact on the nonmetallurgical-grade bauxite component of the industry but may result in significant implications for future international markets and sources of supply for alumina products (Crossley 2003a; Anon. 2003). This may be particularly true for the remaining independent, medium-sized (200- to 300-tpy level) producers of alumina trihydrate, which are currently estimated to number fewer than 20 facilities scattered around the world (Table 16).

The chief influence driving future demand for nonmetallurgical-grade bauxite and specialty-grade alumina will remain the continued general strength and vitality of the world's major industrialized economies and their newly developing industrial competitors, such as China with its explosive levels of industrial growth. It is reported that China currently consumes more steel than the European Union (Cole 2001). Hence, China holds a unique place in the future because of its status as both a major consumer of the world's raw materials and its role as a key supplier of nonmetallurgical-grade bauxite to world markets. The expansion or contraction of these nonmetallurgical-bauxite and specialty-grade alumina markets are very closely tied to the world's basic heavy industry, and it will remain so well into the future.

ACKNOWLEDGMENTS

Many people and organizations contributed greatly to the completion of this chapter by freely providing detailed information on the current status of the world's bauxite and alumina industries. In particular, deepest appreciation is expressed to Patricia A. Plunkert of the USGS, SME, especially Sheryl Tongue, kindly provided greatly needed support with the preparation of the manuscript's more detailed figures. Additionally, Lucy McCartan of the USGS reviewed the final manuscript, and her comments and suggestions are gratefully acknowledged.

Beryllium Minerals

Phillip Sabey

BERYLLIUM AND ITS USES

Beryllium (Be), no. 4 in the Periodic Table of Elements, is a naturally occurring element that is generally reported as the 44th most abundant element in the earth's crust. Beryllium is ubiquitous in the environment and is found naturally in soil, surface and groundwaters, coal and oil, wood, foodstuffs, and gemstones such as aquamarine and emerald. The general population has daily exposure to naturally occurring beryllium from ambient air and drinking water, as well as through dietary intake.

Beryllium was discovered in 1798 by the French chemist Louis Nicolas Vauquelin, who originally named the element glucinium. In 1828, the German scientist Friedrich Wohler extracted it in its metallic form and renamed it beryllium. Beryllium has been an essential material in the manufacture of products for the aerospace and defense, automotive, energy, medical, and electronics industries for more than half a century. It is a unique material that exhibits physical and mechanical properties unmatched by any other metal. On a pound-for-pound basis, beryllium is six times stiffer than steel, making it one of the most rigid metals. It also has two thirds the density of aluminum, making it one of the lightest metals. Beryllium possesses high heat-absorbing capability and has dimensional stability over a wide range of temperatures. Because of its unrivaled combination of qualities, beryllium has become an increasingly important material for a wide range of commercial and governmental applications. For example, hundreds of millions of people worldwide enjoy the benefits of keeping in touch, working more productively, or maintaining communications during emergencies with cellular phones and computers manufactured with beryllium-containing materials.

The commercial value of beryllium was recognized in 1926 when a copper-nickel-beryllium alloy was patented. Application of copper-beryllium alloys, beryllium oxide ceramics, and metallic beryllium grew during World War II in the aerospace and defense, automotive, energy, medical, and electronics industries. The estimated global market value for beryllium-containing materials is approximately \$700 million per year.

Beryllium is a strategic and critical material for many industries and poses no special health risk in the solid form, which is most commonly encountered by the public. The beryllium industry produces three primary forms: the greatest production volumes are of beryllium-containing alloys (e.g., copper-beryllium, nickel-beryllium), followed by beryllium metals, with beryllia ceramics

(beryllium oxide [BeO]) taking third place. Metals such as copper, nickel, and aluminum, when alloyed with small additions of beryllium, may be processed to achieve remarkable combinations of physical properties such as high strength, formability, and hardness. Depending on the desired strength and electrical conductivity, copper-beryllium-wrought products typically contain 0.15% to 2.0% beryllium. Copper-beryllium alloys are designed for and specified in highly engineered applications in the electronics, automotive, household appliance, plastic mold, and aerospace industries because of the unique combinations of such properties as strength, electrical and thermal conductivity, magnetic transparency, and corrosion resistance. The three primary forms of beryllium-containing materials are used as critical, high-reliability components in products such as air bag collision sensors, fire suppression extinguisher sprinkler head springs, x-ray windows for mammography, medical equipment laser bores, pacemakers, landing gear bearings, and weather satellites. Beryllium-containing materials are used in automotive electronics, including the ignition control systems of many modern automobiles, to increase gas mileage, thereby reducing air pollution and generation of global warming gases. Copper-beryllium products are integral for both wired and wireless communications, such as cellular phones and pagers. Other applications include computers, oil exploration equipment, and plastic injection molding dies.

Alloys that are high in beryllium (containing 40% to 100% beryllium) are used for aviation and space applications such as advanced electro-optical targeting and infrared countermeasure devices in fighter aircraft, missiles, and radar systems. Many advanced surveillance and extreme performance satellites also contain beryllium structures and electronic components. Because of its nuclear and mechanical properties, beryllium metal is used in commercial nuclear reactor applications including experimental electricity generation projects such as for fusion reactors and in the construction of nuclear devices for defense applications. Because of its unique property of transparency to x-rays, beryllium metal is used in an extremely thin foil form as the transmission window on high-resolution diagnostic x-ray equipment, and for CAT scanning and mammography equipment. In the fall of 2003, optical-grade beryllium metal was selected as the primary mirror material for NASA's \$825 million James Webb Space Telescope, which, once launched, will allow scientists to see 10 to 11 billion light years away. Beryllium ceramics, produced from high-purity beryllium

oxide powder (99.5%), are used in lasers and electronic packaging for high-speed and high-powered integrated circuits.

Over the years, the range of specific products utilizing beryllium-containing materials has expanded in step with the advance of technology. The demand for features such as higher performance, improved reliability, and miniaturization has created new applications for beryllium-containing materials in high-technology devices. There has been no surge, however, in the number of new end-use markets. In fact, beryllium-containing materials were first used in the major markets as follows

- Maritime, 1930s
- Computers, 1940s
- Aerospace, 1940s
- Telecommunications, 1940s
- Appliances, 1950s
- Automotive, 1950s
- Plastics (molds), 1950s
- Recreational, 1950s
- Dental, 1960s
- Oil exploration, 1960s

The United States is the only country other than China and Kazakhstan that is currently producing beryllium products from beryllium ores and concentrates. Bertrandite, which is mined in Utah, is the principal ore source of domestically produced products. Imported beryl, mainly from Brazil, supplements domestic ore supplies. Table 1 shows world production of beryllium in 2002 and 2003 (estimated).

GEOLOGY OF BERYLLIUM DEPOSITS

Although there are more than 50 beryllium minerals (Barton and Young 2002), only bertrandite, beryl, and phenakite are commercially important. Table 2 gives the compositions of some beryllium minerals. Important beryllium resources occur in several different types of deposits worldwide. Locations of some notable resources are shown in Table 3, along with data on size and grade.

Beryllium in Volcanic Rocks

Although significant beryllium deposits in volcanic rocks are rare, one such deposit at Spor Mountain in Utah is by far the most important source of beryllium in the world. The ore mineral bertrandite occurs as nodules and disseminated fine grains in volcanic tuff. Smaller volcanic rock-hosted deposits have been noted elsewhere in Utah and in Arizona (Shawe 1966), and in New Mexico (Hillard 1969). A deposit of metamorphosed tuff in Australia that is enriched in rare metals is also weakly enriched in beryllium (Taylor, Esslemont, and Sun 1995).

Beryllium in Pegmatites

Granitic pegmatites are the world's principal source of beryl. Beryl has been mined from zones, fracture-filling units, and replacement bodies in heterogeneous pegmatites. The principal beryl deposits are in zoned pegmatites. Most beryl-rich zones contain only a few thousand tons of rock, but a few may contain as much as 1 Mt. Beryl occurs in concentrations of approximately 2% in zones containing plagioclase, quartz, and muscovite, from which mica is the principal product. It is also abundant in zones from which spodumene, amblygonite, and feldspar are recovered.

Beryl tends to be finer-grained in outer zones than in inner zones of pegmatites. Much of the fine- and medium-grained beryl of pegmatites in the Black Hills of South Dakota contains abundant

inclusions of other minerals (Tullis 1952). Large masses of beryl that contain almost no inclusions have been found in inner zones, and these may extend across several zones. Beryl is evenly distributed in some deposits, but in others it is irregularly distributed as rich aggregates in various parts of a zone.

No beryllium minerals in pegmatites other than beryl are of commercial importance because they are exceedingly rare. Chrysoberyl is concentrated in parts of some pegmatites but is much less abundant than beryl.

Beryllium in Quartz Veins

Beryl has been found in quartz veins containing cassiterite, wolframite, molybdenite, scheelite, and other minerals. Such quartz veins may occur in greisen deposits (see section on Beryllium in Greisen in this chapter), and there is considerable overlap between these two deposit types. The concentration of beryl in the outer parts of some quartz veins, just as beryl is concentrated in the outer part of quartz zones in some pegmatites, suggests that these quartz veins are genetically similar to pegmatites. Beryl has been studied in tin veins in South Dakota, England, and elsewhere. Beryl has been reported in quartz veins in Colorado (Adams 1953). Phenakite and bertrandite occur in quartz-scheelite veins associated with beryllium-rich replacement deposits in Nevada (Barton and Young 2002), and bertrandite occurs in quartz-chalcedony veins in Utah (Shawe 1966).

Beryllium in Metamorphic and Replacement Deposits

Metamorphic deposits that contain beryllium are primarily tectites and emerald-bearing schists. Helvite is the chief beryllium mineral

of tactites and related rocks, but vesuvianite, grossularite, chlorite, and possibly other minerals also contain beryllium. The most thoroughly documented beryllium deposits in tactites in the United States are in New Mexico (Jahns 1944) and Alaska (Sainsbury 1963), although the Alaskan deposits are of minor significance. At the Ermakovskoe deposit in Russia, the largest skarn-related deposit in the world, early beryllian vesuvianite skarn was overprinted by late phenakite and bertrandite replacement ore with fluorite and carbonates (Barton and Young 2002). Other significant replacement deposits include beryllium-fluorite deposits hosted by carbonate rocks in Texas (Rubin et al. 1990), Nevada (Barton and Young 2002), and Mexico (Griffitts and Cooley 1978).

Beryllium in Greisen

Greisen vein and replacement deposits in and near granitic rocks may contain beryllium minerals in addition to tungsten and tin. Such deposits are typified by the presence of fluorite and topaz. Productive examples include small but high-grade deposits in Colorado (Hawley 1969) and large, low-grade resources in Kazakhstan (Barton and Young 2002). Beryllium minerals have also been found in the classical greisen deposits of Erzgebirge, Germany, and Cornwall, England.

Beryllium in Alkaline Igneous Rocks

Alkaline igneous complexes, some including nepheline syenite and other nepheline-bearing rocks, have been reported to contain as much as 0.76% beryllium oxide. Several large deposits of this type occur in the Northwest Territories and Labrador of Canada (Richardson and Birkett 1996). Beryllium mineral assemblages in such

deposits are complex. The classical peralkaline syenite complex at Ilmaussaq in Greenland contains a large beryllium resource of unknown grade, and alkaline rocks in the Kola Peninsula of Russia also contain beryllium minerals (Barton and Young 2002). Small quantities of beryllium-rich alkaline rock have been found in Arkansas and Colorado (Warner et al. 1959).

Beryllium in Coal

Beryllium also has been found in coal. Sampling of a variety of U.S. coal ashes indicated a significant distribution pattern for beryllium, with an average of 46 ppm for all of the samples (Stadnicko, Zubovic, and Sheffey 1961). Accumulation of beryllium in coal was determined to be a syngenetic process, and the beryllium content of the coal depends primarily on the rocks that contributed material to the coal-depositional sites.

DISTRIBUTION OF MAJOR DEPOSITS

United States

Because of its strategic importance, beryllium mineral occurrences in the United States were studied extensively in the years after World War II, particularly by the U.S. Geological Survey and the U.S. Bureau of Mines. During this period, the United States did not have a reliable domestic supply of beryllium minerals and relied on imports to supply most of its requirements. Most domestic beryllium was recovered from beryl produced as a by-product of mining other pegmatite minerals. After production of bertrandite began in Utah in 1969, providing the United States with a secure beryllium source, little effort was expended to evaluate additional beryllium mineral deposits.

One method of evaluating the importance of individual deposits is to examine the production record of each deposit. Since 1969, nearly all of the U.S. beryllium mineral production has been from one mine in Utah, and production of beryl has nearly ceased. The few beryl-producing mines that operate are almost all family owned, and production from these mines, which exploit pegmatite deposits, is sporadic. In the late 1950s, however, beryl was recovered as a by-product at as many as 200 operations in 12 different states. Quantities produced during this period ranged from a few kilograms to hundreds of tons. Because of the wide variation in beryl concentrations within an ore body, an individual mine may produce by-product beryl for a few years and then cease beryl recovery entirely.

New England

In general, New England beryllium occurrences are either very small or low grade and as such are not economically exploitable. Pegmatitic deposits in New England are grouped into five major districts, with other scattered occurrences. The major districts are Middletown, Connecticut; Keene and Grafton, New Hampshire; and Topsham and Paris-Rumford, Maine. Additional scattered pegmatites containing beryl occur in western Connecticut, western and central Massachusetts, eastern New Hampshire, and Maine. New Hampshire pegmatites were estimated to contain 1,630 t of beryl (Page and Larrabee 1962). Nonpegmatitic deposits in New England include beryl-bearing granite in western Connecticut, central Massachusetts, and eastern Maine; phenakite-danalite-helvite bodies in granite in central New Hampshire; and beryl-bearing quartz veins in northern Rhode Island.

The principal beryllium mineral in all the deposits except one is beryl, sometimes with associated small quantities of hercynite, bertrandite, beryllonite, or chrysoberyl. Because of ionic substitution of alkali metals in the crystal lattice, beryl in New England generally contains about 12.0% to 12.5% BeO and may contain as little as 9%, significantly less than the theoretical BeO content (Barton and Goldsmith 1968).

Beryllium mineral production in New England was limited to the recovery of beryl as a by-product of mica and feldspar mining in New Hampshire, Connecticut, and Maine beginning in the 1800s, and beryl was recovered sporadically from some of these operations until 1963. Most of the beryllium-bearing mines in New England were small open pits, and mining equipment was minimal.

Colorado

Colorado was one of the largest producers of beryllium minerals in the late 1950s. Much of the production was from a nonpegmatite deposit in Park County. Beryllium was found in dumps of the Boomer mine, a lead-silver prospect dating back to the 1890s, and this led to the discovery of high-grade, vein-type greisen beryllium ore in the old workings. Production began in 1956 and continued for a few years. This was most likely the first nonpegmatite ore mined in commercial quantities. The most important minerals present in the Boomer deposits are beryl and bertrandite (Meeves 1966).

South Dakota

During the late 1950s and early 1960s, South Dakota was the largest beryllium mineral-producing state in the United States. Beryl was recognized in the pegmatites of the Black Hills in the late 1800s, but substantial quantities were not produced until 1914. Most beryl was recovered as a by-product of feldspar and mica mining. Minor quantities of beryl continue to be recovered from deposits in Custer County.

The principal minerals in the South Dakota pegmatites are feldspar, quartz, and muscovite. Beryl was reported in all pegmatite

zones; commercial production, however, was predominantly from intermediate zones. Beryl was reported in fair quantities in the wall zones of certain pegmatites, and production was reported from the core. Both fracture fillings and replacement bodies may contain beryl.

Although some deposits in the Black Hills have been investigated, reserve estimates have varied widely because many deposits were not investigated fully or developed. Runke, Mullen, and Cunningham (1952) published reserve estimates of 13,300 t, with 2,400 t in dump material at 75 properties and 10,900 t in unmined portions of the deposits examined. Mining of beryl for beryllium processing from South Dakota ceased in the early 1990s.

Texas

The Sierra Blanca region in the far western part of Texas was investigated in the 1980s by Cabot Corp. as part of a nationwide beryllium geochemical reconnaissance survey. This region is characterized by five rhyolite bodies enriched in beryllium and other rare metals (Rubin et al. 1987) that intrude sedimentary rocks. Mineralization was emplaced as replacement ore in limestone adjacent to the rhyolite. Beryllium is mainly in bertrandite, but also occurs in behoite, phenakite, berborite [$\text{Be}_2(\text{BO}_3)(\text{OH},\text{F})\cdot\text{H}_2\text{O}$], and chrysoberyl (Rubin et al. 1990). Reserve estimates of these deposits were projected to be 11,300 t of BeO contained in deposits grading more than 2% BeO (Anon. 1986). A test mine was excavated and ore samples were evaluated to determine optimum processing methods, but because of a downturn in the beryllium market, a commercial operation was not started.

Utah

The principal beryllium deposit in the United States is bertrandite-bearing tuff that occurs in western Utah. In 1959, beryllium occurrences were discovered in rhyolitic tuff on the lower slopes of Spor Mountain in Juab County. The beryllium is associated with fluorite, lithium, and uranium minerals, and is regionally associated with topaz rhyolite that is enriched in beryllium and other lithophile elements such as niobium and yttrium (Lindsey 1977). Beryl was reported in rhyolite at Topaz Mountain, a few miles southeast of Spor Mountain, as early as 1905 (Davis 1984). The beryllium ore occurs principally in porous, water-laid Tertiary rhyolitic tuff that is overlain by hard, abrasive rhyolite. The tuff rests on a surface of Devonian dolomite and limestone. Drilling in the area indicated that the tuff ranges in thickness from a few meters to more than 80 m.

Montoya, Havens, and Bridges (1962) studied the chemical, mineralogical, and physical properties of the tuff, and found the analyzed tuff to contain from 0.2% to 1.8% BeO. Two beryllium-bearing minerals were found to be present—a hydrated form of bertrandite and a berylliferous saponite. Each of the mineral forms is predominant in certain areas of the district, but the beryllium is distributed erratically throughout the tuff in individual mineralized bodies.

Brush Resources Inc. began mining this deposit in 1969 by open-pit methods. As the company continues to develop new open pits, resource information on this area is updated. In its 2003 annual report, Brush Resource's parent company, Brush Engineered Materials Inc., estimated its proven reserves to be 6.687 Mt of bertrandite ore at year-end 2003, grading 0.267% Be. Probable bertrandite ore reserves were estimated to be 3.519 Mt grading 0.232% Be.

Other Countries

Brazil

Brazil is traditionally the largest beryl supplier in the international market. The principal beryl-producing areas are the Rio Doce Valley and adjacent areas in the state of Minas Gerais, the Campina Grande District in the state of Rio Grande do Norte, the Critais-Berilândia

District in the state of Ceara, and the Jequitinhonha River Province in the state of Bahia. Soja and Sabin (1986) estimated that more than 106 Mt of ore containing more than 15,000 t of beryllium was present in some properties evaluated in these areas, and almost 99% of the contained beryllium is available from the state of Minas Gerais.

All commercially mined pegmatite deposits in Brazil are complexly zoned or heterogeneous pegmatites. The heterogeneous pegmatites are normally composed of three zones, which are progressively coarser grained toward a quartz nucleus. The intermediate zone contains beryl as well as spodumene, columbite-tantalite, cassiterite, and semiprecious gemstones.

Canada

Beryllium occurrences were first noted in the Thor Lake area, near Yellowknife, Northwest Territories, in 1978. Further geological investigations resulted in the definition of a number of unusual mineral assemblages that appear to be products of the somatic replacement of syenitic and granitic types. Beryllium mineralization, primarily as phenakite, is widespread in all the rock types in the area except the syenite (Trueman, Pedersen, and de St. Jorre 1984). In the mid-1980s, Highwood Resources Ltd. began drilling in the Thor Lake area and identified four different zones—the R zone, the S zone, the T zone, and the Lake zone. Much of the beryllium-rich rock was found in the T zone, and reserves were estimated to be 450,000 t of ore grading 1.4% BeO in the T zone and 1.3 Mt of ore grading 0.66% BeO south of the T zone (Anon. 1985). Preliminary studies indicated that recoveries of 80% to 90% could be obtained, producing a concentrate containing 10% to 13% BeO. Because of difficulties in marketing the products, a mine was never opened at this location.

Large concentrations of beryl and euclase have been reported in peralkaline igneous rocks near Seal Lake in Labrador (Table 3), and a larger (although lower-grade) resource occurs in a peralkaline complex at Strange Lake. The Tanco pegmatite near Lac du Bonnet in Manitoba, which has been mined for tantalum and lithium minerals, is a potential source of beryl, with ore reserves estimated at 920,000 t grading 0.2% BeO (Cerný 1982). The Hellroaring Creek prospect west of Kimberley, British Columbia, is underlain by a beryl-bearing pegmatitic body, with indicated ore resources of 500,000 t grading 0.1% BeO (Schiller 1985).

Russia

The Ermakovskoe deposit in Transbaikalia, Russia, has been an important source of beryllium. The deposit has been described as “skarn-related” (Barton and Young 2002). The ore minerals are mainly phenakite and bertrandite, but the deposit also contains a suite of unusual beryllium minerals as well as beryllian vesuvianite. Beryllium enrichment has also been reported in association with alkaline rocks on the Kola Peninsula and in skarn in far eastern Russia (Barton and Young 2002).

Kazakhstan

Kazakhstan has produced beryllium from an unknown source in recent years (Table 1). Barton and Young (2002) reported the occurrence of beryllium-bearing vein, skarn, greisen, and replacement deposits in the country. The Aqshatau tungsten-molybdenum-beryllium greisen deposits in central Kazakhstan have low-beryllium grades but nonetheless constitute a large resource (Table 3).

China

China is currently the third leading producer of beryllium (Table 1), but little information is available about the source. Beryllium-bearing

vein, skarn, greisen, and replacement deposits are known in the country (Barton and Young 2002).

Australia

Beryllium occurs with zirconium, niobium, tantalum, and rare earth elements in the Brockman deposit, Western Australia, as bertrandite-quartz-carbonate veinlets in metamorphosed tuff. The Brockman beryllium reserves are moderate and low grade. Skarn and replacement tin ore has been reported to contain as much as 0.5% BeO as danalite at Mount Lindsay in Tasmania (Kwak 1983).

Other Occurrences

Beryllium has been recovered from small deposits in many countries throughout the world, but production has been sporadic. In the past 40 years, the countries with the largest contribution to world production outside the United States, Brazil, Russia, China, and Kazakhstan, have been Argentina, India, Mozambique, Rwanda, and Zimbabwe. In the 1990s, beryl from Nigeria was marketed, and in recent years, Zambia and Portugal have produced small amounts of beryllium. Because of the nature of beryl mining, production is subject to internal political and social pressures in individual countries, particularly those in Africa. As a result of limited production, deposits in most other countries are not well documented.

Exploration

In many cases, the presence of beryl is visible by the naked eye. It typically occurs as greenish-white crystals, and because it is usually associated with colorless quartz, large crystals are easily distinguished. For other beryllium minerals and finely disseminated beryl crystals, a beryllometer is normally used in the field for detecting beryllium mineralization. The beryllometer uses gamma radiation supplied by an antimony-124 radioisotope to generate neutrons when the radiation field comes into contact with a beryllium-bearing mineral. This equipment is similar to a geiger counter used to detect uranium. Beryllometers can be made with a sensitivity of 0.01% Be or less. Detection of beryllium in ore is usually followed by diamond drilling and assaying to further delineate beryllium deposits.

Mining

Brush Resources mines bertrandite by open-pit methods at Spor Mountain. Unlike beryl, in which the mineral can be identified by color and crystal structure, bertrandite mineralization cannot be recognized by the naked eye. Consequently, Brush Resources conducts geologic and geochemical evaluations on a specific area, followed by a drilling program to determine if an economic ore body exists.

After delineating an ore body, overburden is removed to within 2 m of the ore by a local earth-moving contractor during the winter and spring. This stripping operation usually requires about 9 months for completion. In the 2-m cover remaining, drill benches are constructed on 7.5-m centers to take samples of the ore body at 0.6-m intervals. Information obtained from analyzing the samples allows cross sections and contour maps to be developed. These maps are used to plan the mining and processing operations.

After the maps are prepared, the remainder of the overburden is removed, and the ore is mined, typically with a self-loading scraper. Because of the irregular ore-grade distribution in the ground, the ore is mined from areas defined by drill data and placed in a stockpile in layers to obtain a more homogeneous blend. Further drilling, sampling, and assaying of the stockpiled ore is then performed to generate a map that delineates ore-grade distribution throughout the stockpile. On the basis of the grade distribution, stockpiled ore is selectively trucked to the mill, which is about 80 km away, for further processing.

beryllium plate. In impact grinding, a high-velocity stream of air blasts a mixture of chips and oversize powder onto a solid beryllium target. On impact, the chips break into small particles that are removed from the chamber by vacuum conveying. A ball mill is used when extremely fine powder is required. After grinding, the beryllium powder is sized, either with screens or an air classifier. Beryllium powder is formed into billets by vacuum hot pressing, hot-isostatic pressing, or cold-isostatic pressing, depending on the end use of the material. Beryllium metal production flow charts are shown in Figures 2 and 3, and specifications are given in Table 5.

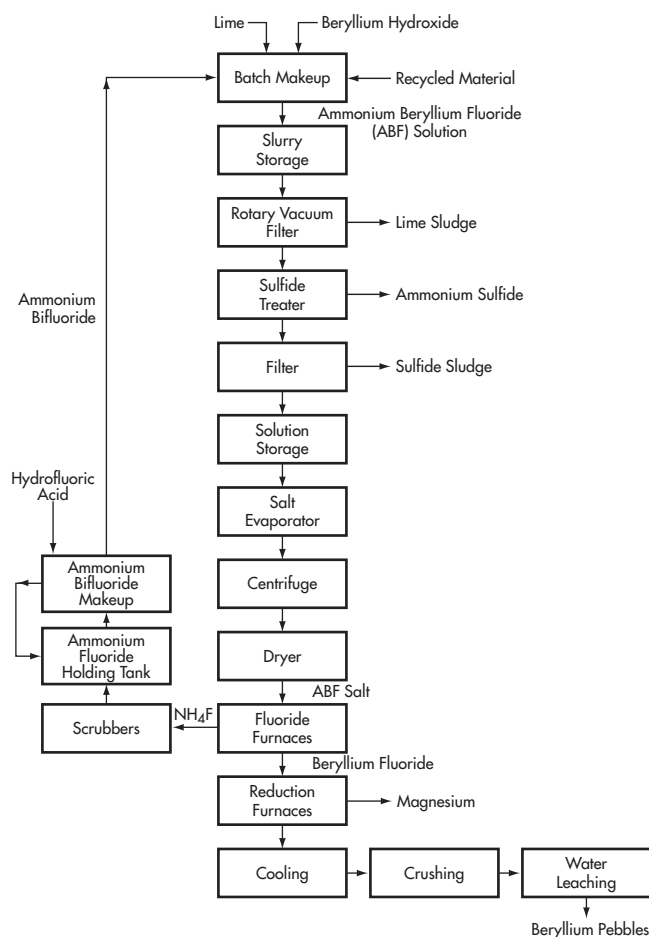

Beryllium Oxide Production

Beryllium oxide powder is produced by dissolving beryllium hydroxide in sulfuric acid. The resulting beryllium sulfate solution is concentrated by evaporation and cooled until the solution is supersaturated. During cooling, beryllium sulfate tetrahydrate crystals are produced. Wet salt crystals are removed from the mother liquor in a centrifuge. Calcining these crystals in a car-hearth furnace at temperatures up to 1,430 °C decomposes the salt to be ryllium oxide, water vapor, and sulfur dioxide (SO₂) and sulfur trioxide (SO₃) gases. The gases are fed through scrubbers, and the beryllium oxide is cooled, screened, and bagged for shipment. Figure 4 shows a beryllium oxide production flow chart.

INDUSTRY STRUCTURE

The United States has the largest demonstrated capacity to process beryllium ore and concentrates into finished beryllium products and supplies most of the rest of the world with these products. As described previously, Brush Resources Inc., a subsidiary of Brush Engineered Materials Inc., mines bertrandite and converts this ore, along with beryl, to beryllium hydroxide at its facility in Delta, Utah. Beryllium hydroxide is shipped to a plant in Elmore, Ohio, operated by Brush Wellman Inc. (another wholly owned subsidiary of Brush Engineered Materials), where it is converted into beryllium alloys and metal. At its Elmore plant, Brush Wellman also produces beryllium oxide, which is further processed into basic ceramic shapes at the Brush Ceramic Products Inc. plant in Tucson, Arizona.

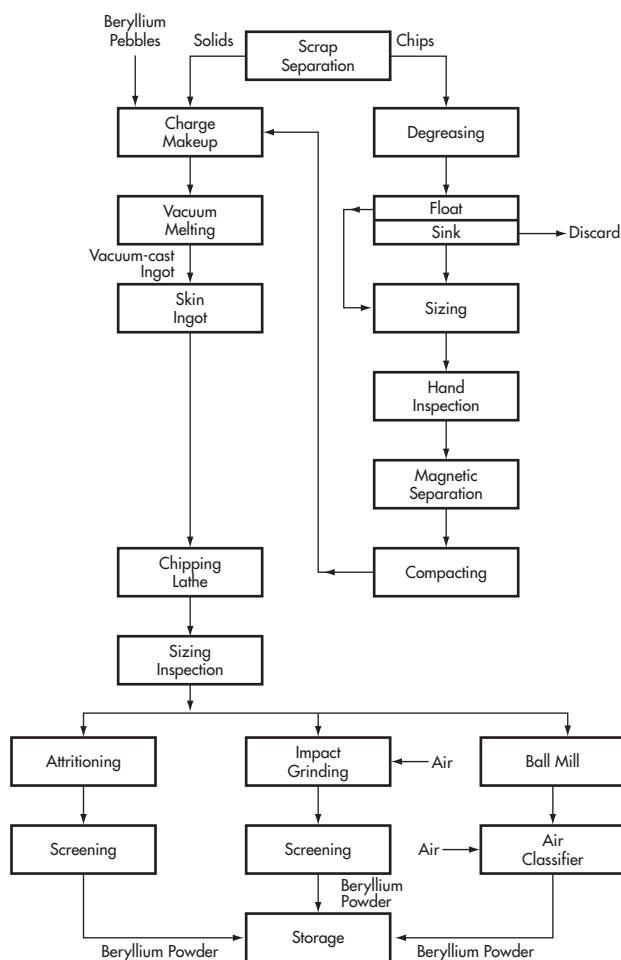

One other company in the United States has the capability to process beryllium alloys. NGK Metals Corp., a subsidiary of NGK Insulators of Japan, produces intermediate forms of beryllium alloys at its plant in Nagoya, Japan. The basic shapes are shipped to a plant in Sweetwater, Tennessee, for further processing and distribution. NGK Metals in Japan reportedly does not have facilities to process the raw materials.

Figure 2. Beryllium pebble production

Ore production from labor-intensive operations outside the United States is sporadic, except for the largest producers in Brazil, China, and some nations of the Commonwealth of Independent States. Before 2000, the majority of the beryl recovered in Brazil was exported to the United States, and Brazil remains the largest

source of beryl imported into the United States. Some beryl ore from China has been imported into the United States in previous years. Recently, China has developed some capability to process beryl and produce some beryllium-copper master alloys. Kazakhstan also has an integrated beryllium industry, based on a stockpile

Figure 4. Beryllium oxide production

of previously mined ores, and has recently restarted operations to market a restricted range of beryllium products.

Beryllium Alloys

Brush Wellman Inc. converts beryllium hydroxide from the Brush Resources mine in Utah into a wide range of alloys of beryllium with copper, nickel, and aluminum at its smelter in Elmore, Ohio. That facility processes the alloys into a wide range of different shapes, such as plate, bar, tube, strip, and wire. Additional strip- and rod-finishing facilities in Reading, Pennsylvania, provide precision finishing capabilities. Currently, Brush Engineered Materials is the only integrated producer of such alloy products in the world.

Copper-beryllium alloys are used in a wide variety of applications and account for approximately 65% of the annual U.S. production of beryllium, on a metal equivalent basis. These alloys, most of which contain between 0.15% and 2% beryllium, are used because of their combination of high electrical and thermal conductivity, high strength and hardness, good corrosion and fatigue resistance, and nonmagnetic properties. Copper-beryllium strip is manufactured into electrically conductive springs, connector terminals, and switches that are used in automobiles, aerospace applications, radar equipment, telecommunications equipment, computers, factory automation devices, home appliances, and instrumentation and control systems. The principal use of large-diameter copper-beryllium tubing is in oil and gas drilling equipment and in bushings and bearings in aircraft landing gear and heavy machinery. Mechanical enclosures and coupling fittings for electronic amplification repeater housings for fiber-optic telecommunications systems represent a significant application for large-diameter copper-beryllium rod and tube stock. Small-diameter copper-beryllium rod and wire is extensively used for the machined miniature sockets that connect integrated circuits to printed circuit boards. Copper-beryllium bar and plate is used in the fabrication of equipment used for the resistance welding of automobile and appliance bodies; for machinery components; for materials handling systems; and for molds used to form metal, glass, and plastic components.

Smaller quantities of beryllium are also used in nickel- and aluminum-base alloys. Electronic connector components that can operate at high temperatures such as those in household cooking appliances and springs used to activate fire sprinklers are leading uses for nickel-beryllium alloys. Aluminum-beryllium alloys are used both in aerospace casting applications and as a master-alloy additive to include small quantities of beryllium in magnesium alloys, which inhibits oxidation during melting operations.

Beryllium Metal

Beryllium metal products, which account for about 20% of the annual U.S. demand for beryllium, are used principally in aerospace and defense applications. The high stiffness, light weight, and dimensional stability over a wide temperature range make beryllium metal useful in satellite and space vehicle structures, inertial guidance systems, avionics, and space optical system components. Because beryllium is transparent to x-rays, it is used in x-ray windows. In nuclear reactors, beryllium also serves as a neutron moderator, in control rods, and as a reflector. Other applications for metallic beryllium include high-speed computer components, audio components, precision electronics processing equipment, and optical scan mirrors. Beryllium metal is used for several applications in NASA's space shuttle, including window and door frames. It is also used to manufacture key components of critical guidance and navigation equipment.

Beryllium Oxide

Beryllium oxide or beryllia is an excellent heat conductor, with high hardness and strength. This material also acts as an electrical insulator in some applications. Beryllium oxide, accounting for about 15% of domestic demand, serves mainly as a substrate for high-power electronic circuits for radio frequency electronics, automotive ignition modules, laser bore components, and radar electronic countermeasure systems. Because it is transparent to microwaves, mobile telephone systems and radar systems also use beryllium oxide.

ECONOMIC FACTORS

Prices

In the past, prices for imported beryl and domestically produced beryllium products were reported by the *American Metal Market*; however, that publication no longer tracks beryllium ores and products. An update on the year-end 2003 prices is not available at this time. After Brush Wellman opened its bertrandite mining operation in 1969, applications for beryllium metal were expanded in the aerospace and nuclear industries. As these new uses were developed, prices remained relatively steady to encourage continued expansion. In the late 1970s, prices escalated rapidly in response to high inflation rates and increased energy costs. At the same time, the U.S. Occupational Safety and Health Administration (OSHA) and the U.S. Environmental Protection Agency (EPA) promulgated new regulations concerning beryllium air emissions. To comply with these regulations, beryllium processing plants were required to install additional pollution control equipment, and the additional costs were ultimately passed on to the consumer. In the 1980s, greater regulation of waste products from beryllium mining and processing increased disposal costs. Again, the increased costs resulted in higher prices for the consumer.

Tariffs and Depletion Allowances

Tariffs for beryl and beryllium products are shown in Table 6. Beryllium ores carry a 22% domestic depletion allowance and a 14% foreign depletion allowance.

Table 6. U.S. import duties*

Tariff Item	HTS No.†	Normal Trade Relations 12/31/03
Ore and concentrate	2617.90.0030	Free
Unwrought beryllium powders	8112.12.0000	8.5% ad valorem
Beryllium, wrought	8112.19.0000	5.5% ad valorem
Beryllium waste and scrap	8112.13.0000	Free
Beryllium-copper master alloy	7405.00.6030	Free
Beryllium oxide or hydroxide	2825.90.1000	3.7% ad valorem
Other	8112.19.00000	5.5% ad valorem

* Ore, metal, scrap, and master alloy: Japan, 28%; Kazakhstan, 24%; Russia, 10%; Brazil, 9%; and other, 29%.

† HTS = Harmonized Tariff Schedule of the United States.

Alternative Materials

Because of its high cost compared with that of other materials, beryllium is used in applications in which its properties are uniquely enabling. Aluminum, magnesium, and titanium alloys, as well as graphite composite materials, may be substituted for beryllium metal in some applications. Many different copper alloys such as phosphor bronzes may be substituted for beryllium-copper alloys. These substitutions, however, can result in substantial loss of performance in some applications, requiring considerable engineering, research, and redesign to compensate for performance loss. Beryllium oxide may, in some cases, be substituted by aluminum oxide or aluminum nitride.

SAFETY REGULATIONS

Beryllium dust and fumes have been recognized as the cause of chronic beryllium disease (CBD), a serious chronic lung disease. The disease was first described by Dr. Harriet Hardy in 1946, before suitable hygienic procedures had been established, among industry employees and their relatives who had handled dusty work clothing. Before modern emission controls came into use, cases of CBD were also reported in the 1940s and 1950s among residents of communities surrounding beryllium-processing plants.

To contract CBD, an individual must be exposed to airborne beryllium in the form of a dust, mist, or fume. This particulate must be small enough (less than 10 µm in diameter) to reach the air sacs deep in the lungs and the individual must be sensitive to beryllium. Not all individuals exposed to airborne beryllium particulate will become sensitized, and of those who become sensitized, not all will develop CBD. Scientists believe that the capacity to develop sensitivity to beryllium is genetically determined and that most people are not susceptible to sensitization.

In recent years, various individuals and organizations have reported that the number of diagnosed cases of CBD has increased since the 1980s. The main factors for this apparent increase are the change in diagnostic criteria for the disease, improvements in medical detection technology, and an increase in the number of workers evaluated for subclinical CBD.

Before the late 1980s, workers were diagnosed with CBD only when they exhibited clinical (observable) symptoms and changes were found in chest x-rays or lung function tests. During the late 1980s and early 1990s, the diagnostic criteria changed, and workers began to be diagnosed without exhibiting clinical symptoms or measurable impairment. Workers diagnosed with CBD in the absence of x-ray or lung function changes or symptoms of disease are referred

to as having subclinical CBD, meaning that they have no clinical symptoms or measurable impairment. This diagnosis became possible through the application of new technology in medical testing and evaluation. Today, workers are typically diagnosed on the basis of sensitization and the presence, on biopsy, of microscopic biological lung formations called granulomas. The biopsy, which uses a procedure called bronchoscopy, is required for obtaining samples of lung tissue. Bronchoscopy with lung biopsy is medically invasive and has its own associated health risks, such as a collapsed lung, bleeding or infection, and a possibility of death.

The natural history of subclinical CBD is not yet known. Workers with subclinical CBD may never develop clinical CBD, or they may develop clinical CBD over time. It is very evident from scientific studies, however, that the incidence of subclinical CBD is higher than the long observed rate of clinical CBD. If most subclinical cases of CBD progressed to a clinical state, historical studies would have shown much higher rates of clinical CBD. It is therefore logical to surmise that in most persons, there is no significant progression of the subclinical disease.

Before the late 1980s, the term "beryllium sensitization" referred to the inflammatory response in the lungs (health effect), which was originally associated with the early stages of clinical CBD. Today, however, the term beryllium sensitization has come into stricter use to describe a positive response to the testing of blood or lung fluid using the beryllium blood lymphocyte proliferation test (BLPT). The BLPT is a laboratory test that measures a level of response when a water-soluble beryllium compound is added to cells isolated from a blood or lung fluid sample. Sensitization does not describe a health effect in the person but rather a response in the blood separate from the person. As detected using the BLPT, sensitization is not an illness or disability, and the test does not detect subclinical or clinical CBD. Competent authorities, such as the American Conference of Governmental Industrial Hygienists, the U.S. Army, U.S. Air Force, and U.S. Navy, have published position papers on use of the BLPT, which recommend that the BLPT not be used for worker screening in the absence of health symptoms.

Although uncertainties related to the cause of the disease still exist, the problem appears to be controlled when established preventive measures are exercised. In beryllium processing plants, harmful effects are prevented by maintaining clean workplaces; requiring the use of safety equipment such as personal respirators; collecting dust, fumes, and mists at the source of deposition in dust collectors; instituting medical programs; and putting other procedures in place to ensure safe working conditions. Control of potential health hazards may add significantly to the final cost of some beryllium products.

OSHA regulates worker exposure to airborne particles containing beryllium. Current OSHA standards limit the 8-hour exposure level to an average of $2 \mu\text{g}/\text{m}^3$ of air, with a peak of $25 \mu\text{g}/\text{m}^3$ not to exceed 30 minutes, and a ceiling concentration of $5 \mu\text{g}/\text{m}^3$. Mine Safety and Health Administration regulations, which are the same as the OSHA standards, affect only the Brush Resources operation in Utah.

Natural and Anthropogenic Sources of Human Beryllium Exposure

The general population is exposed to naturally occurring beryllium from the ambient air, drinking water, and dietary intake on a daily basis. Average ambient concentrations of beryllium in soil range from 2.8 to 5 mg/kg. The average ambient concentration in air in the United States is $0.00003 \mu\text{g}/\text{m}^3$; the median concentration in cities is $0.0002 \mu\text{g}/\text{m}^3$.

Concentrations of beryllium in drinking water range from 10 to 1,220 ng/L with an average of 190 ng/L. The U.S. Agency for Toxic Substances and Disease Registry has estimated that within the United States, about 45% of airborne beryllium results from anthropogenic releases of beryllium. Natural sources such as windblown dust and volcanic activity account for 55% of beryllium released to the atmosphere. Electric utilities generate about 80% of the anthropogenic emissions, and industry and metal mining accounts for about 20%. Beryllium has been measured in rice at $72 \mu\text{g}/\text{kg}$ (fresh weight), lettuce at $16 \mu\text{g}/\text{kg}$, kidney beans at $2,200 \mu\text{g}/\text{kg}$, peas at $109 \mu\text{g}/\text{kg}$, and potatoes at $0.59 \mu\text{g}/\text{kg}$. Beryllium has been found in cigarettes at up to $0.74 \mu\text{g}$ per cigarette. The daily intake of beryllium by nonoccupationally exposed persons from food and water is approximately $0.52 \mu\text{g}$ per day with negligible exposures from ambient air. The average burden of beryllium in nonoccupationally exposed persons is $2.00 \mu\text{g}/\text{kg}$ in the lung, whereas beryllium concentrations in other organs are typically below $80 \mu\text{g}/\text{kg}$.

ENVIRONMENTAL REGULATIONS

Under the Clean Air Act, the EPA has issued standards for certain hazardous air pollutants, including beryllium. Beryllium emissions for plants that process beryllium materials are limited to 10 g of beryllium over a 24-hour period. Plants that machine alloys containing beryllium with less than 4% beryllium by weight are excluded from the hazardous air-pollutant regulations. The EPA regulates beryllium at 4 ppb under the Safe Drinking Water Act.

PROBLEMS AND FUTURE TRENDS

The beryllium industry is rather limited in scale because a single active producer in the United States supplies beryllium-containing materials from its raw material source and processing plants for almost all domestic and most worldwide consumption. Although several other companies have investigated beryllium production as a potential business, it is unlikely that any new plants will be constructed in the United States, primarily because of the significant costs to construct a plant that meets environmental regulations. The commercial outlook for beryllium-containing materials is favorable, especially given their ability to enable end-use products to meet toughening performance demands for weight savings and miniaturization, greater strength, fatigue and corrosion resistance, and thermal and electrical conductivity. Materials producers such as Brush Wellman have continued to work closely with customers in the telecommunications and computer, a automotive electronics, aerospace and defense, oil and gas, industrial components, and appliance industries to ensure new materials are developed in step with advances in end-use product technology. In the past 20 years, for example, Brush Wellman has introduced new proprietary alloys such as Alloy 174, Alloy 60, and most recently, Alloy 390, to serve the market's higher performance requirements. On the metallic beryllium side, the company has introduced AlBeMet, an aluminum-beryllium-metal-matrix composite, to fulfill the unique high performance needs of the aerospace and defense markets.

ACKNOWLEDGMENTS

Much of this chapter was taken from the Beryllium Minerals chapter in the 6th edition of *Industrial Minerals and Rocks* by Deborah A. Kramer of the U.S. Geological Survey (Kramer 1994). The author thanks Ms. Kramer for allowing the use of her work. He also gratefully acknowledges the contributions to this chapter by Marc Kolan, Michael Anderson, Stephen Freeman, and Patrick Carpenter, all of Brush Wellman Inc. The author also would like to thank Stephen B. Castor, Nevada Bureau of Mines and Geology, for

reviewing this chapter and for furnishing information on the geology of beryllium deposits.

Boron and Borates

Steven B. Carpenter and Robert B. Kistler

INTRODUCTION

Boron, element number five on the periodic chart, does not occur alone in nature. Except for a few rare minerals, it is always combined with oxygen. Borates are therefore defined as minerals containing boric oxide or boron–oxygen molecules. These can generally be expressed on the basis of B_2O_3 in combination with a major cation. Borates are sold on the basis of their boric oxide content, and most products and government statistical data are shown in short tons of B_2O_3 (rather than B).

Borates today are used mainly as chemical raw materials in combination with other commodities to produce products used by the ultimate consumers. Fiberglass and glass fibers, glass and ceramics, soaps and detergents, fertilizers and herbicides, and wood preservatives are the major segments of today's market, although more than 25% of the world's borates are used in numerous other consumer products.

Economic mineral concentrations of borates are relatively rare in nature; however, the major deposits now in production are able to adequately supply the existing markets at reasonable prices. Currently, the United States and Turkey supply more than 75% of the world's markets from deposits that are found in Neogene age (<24 million years), continental sediments.

The mineral borax may have been known by ancient civilizations, but the first authenticated use of borates was as a flux for assaying and refining precious metals in the 8th century AD. China was probably the first country to consistently use borates in medicines and ceramics from about 1000 AD (Smith 1997); the borates used were mined from spring deposits and salars or dry lakes in Tibet. Marco Polo claimed to have brought the first borates from China to Europe, and his home port of Venice became the center for fine work in gold, ceramics, and glassware. The use of borates to make these items was a well-guarded Venetian "trade secret" for many years. Elsewhere in Europe, alchemists, and later the medical profession, used small amounts of borates, but the price was high (as late as 1790 the price of refined borax was about \$3/oz in London) and the source of this rare mineral commodity remained mysterious.

Tibet continued to be the source for most borates until the beginning of the 19th century when sassolite was discovered around the fumaroles of Larderello, near Pisa, Italy. Commercial production began there in 1808, and this area soon replaced Tibet as the major western source of borates. The discovery of borates in

the desert marshes of the New World, in both North and South America in the mid-19th century and their subsequent popularization by F.M. "Borax" Smith and others, helped lower the price and expand usage into consumer products, especially soaps and detergents. By 1890, borates were readily available in Europe and the United States at about \$75/t. Finally, the discovery and development of major bedded deposits during the 20th century, first in Death Valley and later at Boron, California, and in Turkey, enabled this once rare mineral to expand into the major, worldwide commodity that it is today.

PRODUCTION AND TRADE

Commercial borate production is centered in southern California, western Turkey, northern Argentina and Chile, southern Bolivia and Peru, eastern Russia, and northeastern and west-central China (Figure 1). The major materials sold are borax pentahydrate (5 mol) and decahydrate (10 mol) and boric acid, followed by colemanite and ulexite mineral concentrates.

The United States is the leader in production of refined borates and boric acid; about half of the domestic production is exported (Table 1). Turkey is the world's major supplier of mineral concentrates and also produces large amounts of boric acid and refined borates. Almost 90% of their production is sold on the export market.

South American production has usually been sold into Brazil and other countries in the southern hemisphere, with sales mainly for agriculture and ceramics. Recently increased production, however, particularly of boric acid, has moved sales into Asia and North America, generally where price is the major consideration.

Russia produces mainly boric acid from their unique borosilicate deposit near the Sea of Japan. Historically, the former U.S.S.R. sent this production by rail as far west as eastern Europe, but with the changing economic climate and their advantageous position near tidewater, some of their boric acid now goes to China, South Korea, and Japan. Chinese borate production is from a number of relatively small mines in both the western and the northeastern parts of that country. Their borate production has yet to equal their internal demand, and most of the Chinese borates are sold within the country; they do, however, export some product to India, Pakistan, Indonesia, and South Korea (Table 2). Figure 2 illustrates current consumption of borates, broken down by end use, in both the United States and the world.

GEOLOGY

Mineralogy

More than 200 minerals contain boron, but only a few are commercially important (Table 3). The majority of borate minerals can be divided into three groups for ease of discussion: sodium and calcium borates, magnesium borates, and borosilicates. In general, sodium and calcium borates are formed under near-surface conditions as a result of volcanic activity and are associated with continental sediments and volcanic rocks. Magnesium borates are most often found with marine sediments, whereas borosilicates are associated with metamorphic and igneous rock and mineral assemblages.

Borates commonly occur with the following elements—arsenic, antimony, calcium, iron, lithium, magnesium, manganese, silica, and sodium—and zeolite minerals. There is also an apparent association with some metals such as gold, iron, and zinc, depending on the geologic setting.

Tests

The early prospectors' test for borate was to wet the sample with sulfuric acid and a little alcohol and light the fumes; "She burns green!" was the result of a successful test. Wetting a sample with specially prepared turmeric or cobalt-nitrate solutions also provides quick positive or negative field test results. Today, most commercial laboratories detect and identify borates using atomic absorption (AA) or inductively coupled plasma (ICP) methods.

Chemical Properties

Boron has the valence state 3+. It forms very strong covalent bonds with oxygen and links with either three oxygen atoms to form triangular planar BO₃ groups or four oxygens to form tetrahedral BO₄ groups (Smith and McBroom 1992). These groups can link together by sharing oxygen atoms to form rings, cages, chains, sheets, and networks. The resulting borate structures possess a negative charge equal to the number of BO₄ groups they contain, because these have a formal 1– charge. As a result, borates form salts and double

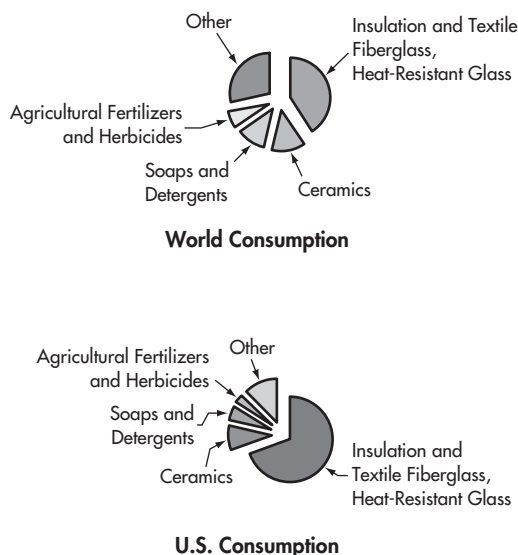

Figure 2. Estimated world and U.S. borate consumption by major end use

Table 3. Commercially important borate minerals

Mineral	Chemical Composition	Wt % B ₂ O ₃
Borax (tincal)	Na ₂ B ₄ O ₇ •10H ₂ O	36.5
Boracite (stassfurtite)	Mg ₆ B ₁₄ O ₂₆ C ₁₂	62.2
Colemanite	Ca ₂ B ₆ O ₁₁ •5H ₂ O	50.8
Datolite	CaBSiO ₄ OH	24.9
Hydroboracite	CaMgB ₆ O ₁₁ •6H ₂ O	50.5
Kernite (rasorite)	Na ₂ B ₄ O ₇ •4H ₂ O	51.0
Kurnakovite	Mg ₂ B ₆ O ₁₁ •15H ₂ O	37.3
Pinnoite	MgB ₂ O ₄ •3H ₂ O	42.5
Priceite (pandermite)	CaB ₁₀ O ₁₉ •7H ₂ O	49.8
Probertite (kramerite)	NaCaB ₃ O ₉ •5H ₂ O	49.6
Sassolite (natural boric acid)	H ₃ BO ₃ 56.3	
Szabelyite (ascharite)	MgBO ₂ OH	41.4
Tincalconite (mohavite)	Na ₂ B ₄ O ₇ •5H ₂ O	47.8
Ulexite (boronatocalcite)	NaCaB ₅ O ₉ •8H ₂ O	43.0

salts with various cations and with interstitial water (Chang 2002). Hydrated borates contain B–OH groups, O[−] groups, or water.

The common borates are slightly basic with a pH of 7 to 10. Their solubility curves are fairly normal from about 50° to 120°C (Garrett 1998). Borax (10 mol) is readily soluble in water and will lose 5 mol of water under summer desert conditions to form tincalconite (natural 5 mol). Ulexite and colemanite are only slightly soluble in water under atmospheric conditions but dissolve rapidly in acid. The Russian borate ore minerals, datolite and danburite, and the principal Chinese borate ore, szabelyite, are acid soluble.

Origin and Modes of Occurrence

Borates are present in low concentrations in most soils and in many rock types. Borates in soil tend to collect on micas and in the molecular lattice of clays in concentrations of <10 to >150 ppm B. The average concentration in surface streams is reported to be about 0.1 ppm, and in seawater averages about 4.6 ppm (Sprague 1972).

Borate deposits throughout the world are found in tectonically active, extensional terrains near subducted plate boundaries. They are associated with calc-alkaline extrusive rocks, tuff, tuffite, limestone, marl, claystone, gypsum, and continental silts and sands; the ultimate source of the boron, however, is still under discussion. The boron may be leached from marine sediments in the mio- or eugeo-synclinal continental margins or from earlier granitoids and brought to the surface by volcanic activity associated with the subduction of plate margins (Kasemann, Erzinger, and Franz 2000). Others suggest that the B₂O₃ may be leached from the surrounding rocks; local ignimbritic volcanism is considered the source for the Kirka deposit in Turkey (Floyd, Helvacı, and Mittweide 1997). Limited field investigations by the authors indicate that rocks surrounding and down-dip from known deposits are usually low in boron and show no signs of having been leached, which casts some doubt on local, near-surface crustal sources for most North American borate deposits.

Most of the commercial-grade borate deposits worldwide are associated with continental sediments. These can be divided into spring and spring-apron deposits, playa or salar accumulations, and lake deposits, although there is a gradation between these categories.

All the major “world class” deposits in North America and Turkey are found within Neogene lake sediments that are associated with contemporaneous faulting and volcanism. The borates within these lake sediments appear to be chemical precipitates that formed as the concentration of boron in the lake waters reached temporary saturation levels, either because of changes in the evaporation rate or from periodic influxes of boron-rich waters from nearby springs. Precipitation of the primary borate minerals appears to be controlled by pH. Borax precipitates at a higher pH than ulexite and colemanite forms as a primary mineral at a slightly lower pH and warmer temperature (Helvacı and Orti 1998).

The Searles Lake brines, a major borate source in the United States, are unusual in that they have resulted from the progressive concentration and decanting of salts from springs quite a distance from the lake (Smith 1979). A local spring source associated with the tuff cones within the lake itself may, however, also have furnished at least some of the salts, including the borates.

Neogene to Recent age salar or playa borate deposits, mainly ulexite, are an important borate source in South America and China. The Recent age deposits have near-surface water tables, fed by springs that appear to furnish the borates. Depositional control is related to spring outflow, borate concentration of the water, pH, and possibly changes in pressure. These deposits are within currently active volcanic belts associated with plate subduction boundaries.

Some accumulations of borates are directly associated with active hot springs or fumaroles. Larderello in Italy and Clear Lake in California are examples; others such as Antuco in Argentina and many of the Tibetan sources are formed from spring waters cool enough to be frozen during part of the year. It is clear that surface water temperatures are not as important as borate content.

Borate deposits associated with marine sediments appear to form in near-shore bays, possibly enhanced by borate springs. The borate-enriched seawater is concentrated during desiccation and compaction of the sediments, resulting in the deposition of the primary borates. Some accumulations of marine borates are further concentrated during uplift, by erosion or dissolution of the associated salts.

Igneous and metamorphic borate concentrations are formed from hydrothermal solutions that accompany granitoid intrusions. There is no universal agreement on whether the borates are in the magmatic fluids or if the fluids act on and incorporate borate-containing calcareous sediments.

Figure 3. Major U.S. borate deposits

Courtesy of Courtesy of U.S. Borax Inc.

Figure 4. U.S. Borax's open-pit operation at Boron, California

The Paleoproterozoic borates of Jilin and Liaoning provinces in eastern China appear to be sedimentary borates that have been metamorphosed by the intrusion of later granitic plugs (Peng and Palmer 1995). Other investigators subscribe to a granite-related metasomatic source for these deposits (Wang and Xu 1964).

In the Bor deposit in Russia, the source is clearly of magmatic origin (Ratkin and Watson 1993). The calcareous host sediments were further altered by later brines heated by a second series of intrusions (Malinko 1992; Hamet and Stedra 1994), resulting in a relatively high-grade borate skarn. Sullivan, B.C., Canada, where a high-boron tourmaline skarn is associated with a large zinc deposit, might be an example of either metamorphic or magmatic action.

Distribution of Major Deposits

North America

Almost all of the known borate deposits in the United States are found in southern California and adjacent portions of Nevada (Figure 3). The only other known North American borate deposit is in the northern part of Sonora, Mexico. All of these deposits are of Neogene age and are associated with continental sediments and volcanic rocks.

United States. United States production is dominated by the Kramer borax and kernite deposit located at Boron, California, midway between the towns of Barstow and Mojave, and by the borate-

containing brines of Searles Lake, which is located about 65 miles north of Barstow.

U.S. Borax, Inc. (Rio Tinto) mines the large Kramer deposit at Boron by open-pit methods (Figure 4). The ore body consists of lake sediments containing up to 90% borax, some of which has been converted to kernite by the pressure of burial. The borates are within a thick sequence of Miocene-age continental sediments, protected from dissolution by a surrounding series of greenish marls and clays. The deposit is underlain by olivine trachybasalts and overlain by up to 300 m of Miocene-age silts and arkosic fanglomerates. Faulting, some of which was penecontemporaneous with mineralization, has offset portions of the ore body. The ore is refined in an adjacent plant where a full range of sodium borate and boric acid products are produced. Specialty borate products are made at Borax's Wilmington plant and shipping facility located at the Los Angeles harbor.

Searles Lake, a Holocene salar (approximately 40,000 years old), contains both bedded salts and brines that reach thicknesses of more than 40 m and extend over several tens of hectares. Searles Valley Minerals, Inc. selectively pumps the brines from several of the salt layers and refines them in the ir plants near the town of Trona on the west side of the lake. These brines supply other commercial salts in addition to sodium borates and boric acid.

Death Valley continues to produce limited amounts of colemanite and ulexite/probertite concentrates from a relatively small underground mine located on the east side of Death Valley National Park. The American Borate Company (ABC) operates this mine, the Billie. None of the other small borate deposits in or around the park is currently being mined. These deposits are all dated at between 5 and 8 Ma.

Fort Cady Minerals Corporation maintains a small acid-solution mining project at Hector, about 30 miles east of Barstow. This Neogene-age colemanite deposit is injected with sulfuric acid that is pumped to a nearby plant, and calcium meta-borate is precipitated. As of 2004, this plant was on standby status. No other borate deposits are in production in the United States.

Mexico. U.S. Borax and Vitro MEX discovered a small colemanite deposit near the town of Magdalena, Sonora, in 1972 (Aiken and Kistler 1992). It is not currently in production.

South America

At least 30 borate sources in South America are producing or have produced borates. These are all located on the high Andean *altiplano* or *puna* near the common borders of Argentina, Bolivia, Chile, and Peru (Figure 5). South American borate producers have historically sent much of their production to Brazil, with smaller amounts going to other countries within the Latin American economic trade zone. Most of this production has been borax and ulexite concentrates. Within the last 10 years, however, many of the larger producers have constructed boric acid plants and expanded their markets to include Taiwan, China, Japan, and portions of the United States and Europe.

Argentina. All of the known Argentine borate deposits are located in northwestern Argentina. For many years, South American borate production has been dominated by the Tinicalaya open-pit borax mine of Borax Argentina (Rio Tinto). This Late Neogene, tectonically deformed, playa deposit (5 to 6 Ma) is located in Salta Province near the Salar de Hombre Muerto. Borax Argentina also mines Neogene-age ulexite, hydroboracite, and colemanite at Sijes, close to Salar Pastos Grandes, and Holocene ulexite from several salars in Salta and Jujuy provinces. Their main processing plant and new boric acid facility are located at Campo Quijano, near the city of Salta.

Procesadora de Boratos Argentina (PBA) operates a Neogene borax and ulexite deposit at Loma Blanca near Coranzuli in Jujuy Province and their plant is located at Palpala, near the city of Jujuy. At least seven other active borate mines are on the Argentine *puna* in Salta and Jujuy provinces, all based on Holocene-age salar ulexite deposits; none of them furnishes large amounts of production.

Bolivia. The borate industry in Bolivia centers on several salar deposits in the southern portion of the country and on the southern edge of Salar de Uyuni (Figure 6). Ulexite is the ore mineral in these deposits. The major producers are Cia Minera Tierra Ltda. with salar operations at Laguna Capina, Chalhvi, and Pastos Grandes, and two companies that operate on the southern edge of Uyuni, Minera Rio Grande and Non Metallic Minerals, the latter a venture between D. Moscoso and the Chilean borate producer Quimica y Industrial del Borax (Quiborax). Non Metallic is currently the largest borate producer in Bolivia with production capacity of 100,000 tpa. At this time there is no production from the brines of Salar de Uyuni itself. Most of the ulexite mined in Bolivia is exported as a mineral product. Tierra is the only Bolivian producer of boric acid. Their 15,000-tpa plant located at Apacheta uses geothermal heat from the nearby Laguna Colorado hot springs.

There have been a number of stories about the local borate industry in the past decade or so. In 2001, the Bolivian government temporarily shut down Tierra's boric acid facility for supplying acid to the cocaine trade. In mid-2004, the government revoked the mining concessions of Non Metallic Minerals for evading customs taxes. The latter charge is being fought in the courts. Both instances indicate a heightened interest in this long-neglected corner of the country by the central government and are a sign that borates are becoming a more significant Bolivian export.

Chile. The Chilean borate producers are all located in the northern portion of the country. The largest, Quiborax, produces a number of products, including boric acid, from their plant outside Arica and their newly purchased boric acid plant in Antofagasta. Their main resource base is Salar de Surire near the Bolivian border. Other smaller operations are located on Salars Ascotan and Pajonales.

Sociedad Quimica y Minera de Chile S.A. (SQM) produces boric acid from their large brine deposit on Salar de Atacama as a by-product of their lithium and potassium sulfate production. There is also a small, independently owned boric acid plant located at Iquique.

Peru. There is one major producer of borates in southern Peru, Industrias Bitossi S.P.A., which is based in Arequipa; Laguna Salinas is their ulexite source. They produce ulexite concentrates, much of which is shipped from the port of Matarani to Lardarello in Italy under the Inkabor label. They also produce boric acid.

Eurasia

Turkey is the world's major borate producer outside of the United States. Their borate sources include the world's largest known deposits of borax, colemanite, and ulexite. These are all Neogene age, continental lake-bed deposits located in the northwestern part of Anatolia.

Chinese production is from Paleoproterozoic metasediments and metavolcanics in Liaoning and Jilin provinces, northeast China, and from Holocene-age salars in Qinghai and Xizang provinces, western China. Russian production comes from Bor, a unique metamorphic deposit located near the Sea of Japan. The borate production in Kazakhstan, north of the Caspian Sea at Inder, ceased in 2003.

Turkey. All Turkish borate production is currently under the control of Eti Holdings, a state corporation. They produce from five distinct areas: Kirka, the Emet Valley, Kestelek, Sultancayiri, and the Bigadic Basin (Figure 7). The deposit at Kirka consists of

Figure 5. South American borate deposits

Courtesy of Robert Kistler.

Figure 6. Ulexite mining at Rio Grande, Bolivia

borax, up to 145 m thick, with light green to white intercrystalline carbonates and clays; the deposit is capped by a porcelaneous limestone (Helvacı et al 1993; Kistler and Helvacı 1994). Mining is by open-pit methods. The ore is processed locally and sent by truck and train to the port of Bandırma.

Eti also produces from two large colemanite deposits in the Emet Valley north of Usak, where the ore is interbedded with limestone, and from two smaller colemanite deposits at Kestelek and Sultancayiri, south of the Sea of Marmara. These deposits are mined mainly by open-pit methods. The large bedded ulexite-colemanite deposits in the Bigadic Valley south of Balıkesir occur in two distinct geologic units separated by a thick tuff (Helvacı and Yagmurcu 1995). These deposits are mined by both open-pit and underground methods. All the Turkish deposits currently being mined range in age from 16 to 19 Ma.

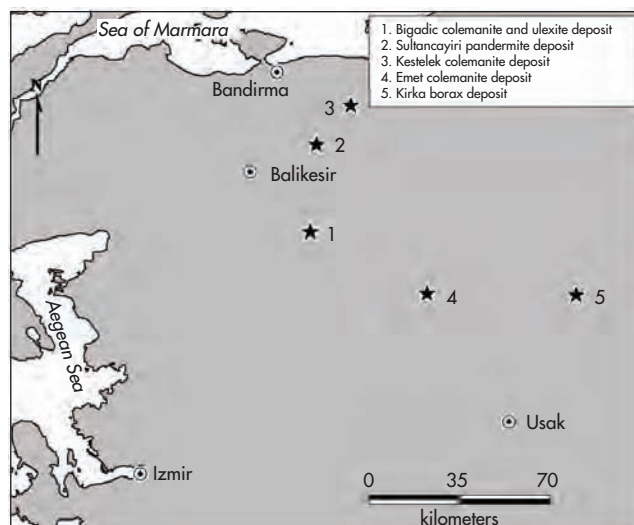

Figure 7. Borate districts of Western Turkey

Eti has constructed boric acid plants at both Emet and Bigadic, but their main processing plants are at the shipping port of Bandirma on the Sea of Marmara. They sell a full range of borate products, including both colemanite and ulexite concentrates as well as sodium borates and boric acid; more than 90% of their production is exported.

Europe. There is no reported borate production from Europe at this time. Historically, borates were recovered as a by-product of potash mining from the Zechstein Group in eastern Germany but they are no longer being produced. The borates discovered in the Jarandol Basin of Serbia and held by Electropriroda Srbije, the state electric company, are not yet in production because of continuing political problems in that part of the world. Larderello, near Pisa, Italy, no longer reclaims commercial borates from fumaroles, although the facilities there continue to produce boric acid from imported material.

Asia

China and Russia are the major suppliers of borates from Asia (Figure 8). Kazakhstan, Iran, India, Tajikistan, and North Korea all have reported borate occurrences; some of these countries may produce very limited amounts of borates for internal consumption.

China. Chinese borate production originates from two geologically and spatially distinct areas. Paleoproterozoic sequences of metasediments and metavolcanics in Liaoning and Jilin provinces, northeast China, are the source of more than 94% of China's current borate production. These deposits contain magnesium and magnesium-iron borates that are mined by underground methods. More than 20 plants convert these borates into borax and boric acid, which is sent, mainly by rail, to the major manufacturing centers. Most of this production is near the cities of Yingkou, Fengcheng, and Dandong. It is mostly consumed internally, although there are some exports to the neighboring countries of Pakistan, Indonesia, North Korea, and India. The glass and porcelain enamel industries are the main consumers of borates in China.

Lake terrace and salar-type lake-bed deposits of kurnakovite and borax are mined in Xizang (Tibet) Province, and lake-bed ulexite and pinnoite is mined in Qinghai Province. Mining is by labor-intensive methods and on a relatively small scale. These

Figure 8. Current Asian borate producers

borates are shipped to manufacturing centers in eastern China by truck and rail.

Russia. The only major source of borates in Russia at this time is the unique Bor deposit, a large skarn accumulation with datolite and danburite as the major borate minerals, located at Dalnegorsk near the Sea of Japan. The two distinct stages of borate skarn mineralization have been loosely dated at 55 and 35 Ma (Malinko 1992) and >64 Ma (Ratkin and Watson 1993). This deposit, which is mined by open-pit methods, is now under the ownership of JSC Energomash-Bor. Their major product is a high-grade boric acid, much of which is railed to western Russia, although some is shipped to China, South Korea, and Japan.

Russian scientists have identified a number of small skarn borate deposits, many near the Ural Mountains (Alexeev and Chernyshov 1997), which produced sporadically until the late 1970s. These are apparently not in production at this time.

Kazakhstan. The marine borates at Inder, located just north of the Caspian Sea in the far western part of Kazakhstan, are associated with a series of large, Permian-age salt domes. These deposits, consisting mainly of nodular ulexite and hydroboracite, were at one time the major source of borates for the former U.S.S.R. The shallow, easily recovered reserves are exhausted, and, as of late 2003, there was no borate production from Inder. A deposit in a similar geologic setting has been identified by drilling about 100 km to the north at Satimola, but it is not currently in production.

Other Areas. There are no known borate deposits on the continent of Africa, in Australia, or in Indonesia, although hot springs with elevated boron values have been identified in New Zealand. Borate-rich springs have long been known in the Puga Valley of India, but they are too low grade to permit commercial exploitation at this time. The borosilicate deposits in the high mountains of southern Tajikistan are very remote, and the danburite ore would be difficult to refine economically. North Korea has reported low-grade ludwigite bodies southwest of Pyongyang. Iran has several small colemanite showings that are handpicked for a few tons each year, which are consumed by local ceramic manufacturers.

TECHNOLOGY

Exploration Techniques

The search for undiscovered borate deposits continues in many parts of the world. Governmental geologic surveys, major corporations, and prospectors are involved in this search, some using the latest in

scientific methods and data searches. Others, particularly in the less developed areas of the Far East, continue with the time-tested methods of outcrop evaluation that have been used for hundreds of years.

The borates of commerce (borax, ulexite, and colemanite) are the most commercially valuable and are the exploration target of choice in areas where the geology is permissive. These are usually buried under protecting layers of associated sediments and volcanics. As a result, the more recent borate exploration techniques concentrate on indirect detection of buried targets.

Satellite imagery can detect surface and near-surface exposures of clays, limy sediments, and salts as well as borates themselves. These surveys are most useful in areas with little vegetative cover, such as Death Valley, where these studies have been pioneered (Crowley 1993). Geophysical methods, including seismic, magnetic, and gravity surveys, are used as indirect indicators of borate deposits, generally in areas with known structures or deposit controls.

Geochemical methods for indicating borates have been used for some years. Boron is a relatively mobile element and can be detected in soil and rock samples to <10 ppm, and to <1 ppm in water. Typical indicator elements include arsenic, antimony, beryllium, fluorine, lead, lithium, magnesium, and strontium, but boron values usually provide the best indication of a nearby borate deposit. Geochemical prospecting methods utilize concentrations and ratios of the more mobile elements in combination with boron values.

Basic geologic evaluations of permissive areas and outcrops by mapping and sampling followed by drilling remains the best, but most time consuming, exploration technique. Drilling methods vary by area, target and target depth, and drill availability.

Evaluation of Deposits

Borate deposits are evaluated on the basis of their B₂O₃ grade, mineralogy, mineral recovery, and projected sales targets. As previously noted, most of the borate deposits that remain to be discovered in the western hemisphere are buried under protecting layers of sediments and volcanics. Evaluating these deposits usually requires drill testing followed by bulk sampling. Because these borates are susceptible to leaching, drill-sampling procedures using air recovery or larger diameter core are preferred to small-diameter coring methods.

In some areas, surface trenching and channel sampling of anomalous sediments are a cost-effective method of evaluation. For more deeply buried deposits, large-diameter core samples are used to obtain bulk samples for initial tests. Limited underground work or small-scale open-pit tests then provide the bulk samples for final mine and mill design.

Mining

Most of the major borate deposits in the world are now mined by open-pit methods, generally using truck and shovel or backhoe equipment. In the United States, only ABC in Death Valley operates underground at this time. Several mines in Turkey and all of the ones in eastern China are mined underground using labor-intensive methods. A few of the South American and Chinese salars continue to use hand-mining methods to recover the thin borate layers. Searles Valley Minerals in the United States and FMC in Chile produce borates by pumping and refining complex brines; Fort Cady Minerals, also in the United States, uses acid dissolution of in situ colemanite as their mining method.

United States

The boron open-pit mining operation of U.S. Borax operates a fleet of 260-st unit-rig trucks and several P&H 4100 electric shovels with 58-yd³ buckets as their main mining equipment. Mining

benches are 17 m high. The ore is currently trucked to a surface primary crusher.

In Death Valley, ABC mines colemanite and probertite from depths of 230 m to more than 300 m below the desert surface using conventional drill-and-blast methods and backfilling of stopes.

Searles Valley Minerals pumps brines from several salt layers, up to 100 m deep, in Searles Lake, and then injects spent plant liquor back into the formation to improve recovery. At Hector, Fort Cady Minerals injects weak sulfuric acid into various levels of their bedded colemanite deposit, which is more than 300 m deep, and recovers calcium metaborate from the solution.

South America

Borax Argentina and PBA both mine their borax deposits by open-pit methods, using relatively small front-end loaders and 24-st trucks. All the major operators (Borax, Quiborax, Tierra, and Bitossi) use tracked backhoes to strip and mine their salar ulexite deposits. The ulexite is then transported by small trucks, or wagons pulled by farm tractors, to drying areas off the salars. Smaller operators continue to use hand methods to mine, turn, and sun-dry the wet ulexite recovered. The major producers also have adopted mechanically aided drying methods. The dried ulexite is then trucked, or in some cases railed, from the salars to processing plants that are generally located near major towns where water and power are available. SQM pumps brine from Salar de Atacama and concentrates the salts by solar evaporation before introducing them into their plant. They produce other commercial products in addition to borates.

Turkey

Eti Holdings mines the large Kirka borax deposit by open pit, using truck-shovel methods for both mining and overburden removal. Similar methods are used for their colemanite mines in the Emet Valley. The smaller colemanite deposits at Sultançayırı and Kestelek have been mined by both open-pit and underground methods, using relatively small equipment. The major ulexite/colemanite deposits in the Bigadic Basin also are mined by both open-pit and underground methods.

China

Privatization of the Chinese borate industry has resulted in production from a large number of relatively small deposits. The hard-rock deposits in Liaoning and Jilin provinces are mined by underground methods. These underground mines use conventional drilling and blasting with some hand tramming, and many use rail declines from the surface. Almost all of these mines have nearby mills where the ore is converted to borax or boric acid, which is then shipped mainly by rail to the manufacturing centers of eastern China.

The salar deposits in Qinghai and Xizang provinces are worked mainly by hand, although a few now use small backhoes. Production from this area moves by truck to centralized railheads and then by rail to processing plants in eastern China.

Russia

The Bor deposit in far-east Russia is mined by open pit. During the last visit by the authors, it was observed that older model Russian trucks and shovels were still being used. The ore is trucked to an adjacent boric acid plant. Much of Russia's boric acid production is still shipped by rail to the Moscow area; exports are shipped from the small, nearby port of Rudnaya Pristan.

Processing

The basic processing steps used to convert most borate ores into either sodium borates or boric acid, the main products consumed by

Table 4. U.S. borax typical product grades and specifications, ppm

Type	% B ₂ O ₃	SO ₄	Cl	Fe	As	Insol
Anhydrous borax (AB)	68.5	<150		<40		
Pentahydrate (5 mol)	49.3	<100	<120	<10		<400
Decahydrate (10 mol)	38.3	<600	<700	<30		
Boric acid, technical grade	59.1	<3.0	<0.4	<2.0	<0.2	<10

other industries, are as follows: (1) crushing the ore; (2) dissolving the ore mineral in either heated water if borax or kernite is the ore, or in acid if ulexite, colemanite, or other borate mineral is the ore; and (3) precipitating the product, either boric acid or sodium borate. The wet recovered product is then dried, screened, and prepared for shipment in either bag or bulk (Table 4). Most of the South American salar ulexite producers sun-dry their ore before processing, and SQM in Chile uses the sun to concentrate their brine before plant processing. Almost every major processor has a plant design specific for that ore and that location; these processing plants are discussed in some detail in works by Garrett (1998).

Marketing

Marketing is tied to the consumer with products specifically designed for the needs of major customers. Price and service after the sale are becoming an increasingly important part of the business.

Borates are an essential component of many items. Without borates, many products would be inferior, and some could not be produced in their current form. The principal uses are in insulation-grade glass fibers, textile-grade glass fibers, heat-resistant glass, soaps and detergents, fertilizers and herbicides, enamels, frits and ceramic glazes, wood preservation, and cellulose insulation. The many other uses include fire retardants, metallurgy, specialty paints, nuclear applications, taxidermy and embalming, sports products, batteries, high-intensity magnets, and specialty chemicals.

Competitive products have eroded some markets in the soap and detergent field, in lower-grade ceramics, in some types of glass fibers and in some fire retardants. These losses have been more than recouped by the many new uses.

Product Pricing

Prices for borates (Table 5) have been flat for the past few years, reflecting competition in the marketplace and a balance between supply and demand. Prices for the various products reflect the energy cost of refining and drying.

Transportation and Distribution

United States

Borates are a lightweight, low-bulk-density commodity, and thus sales are usually made in carload lots. Because of the purity specifications and solubility of manufactured borate products, both major U.S. producers have their own fleets of railcars dedicated to the exclusive shipment of product. For U.S. Borax, unit trains transport refined borates from Boron to their facility at Wilmington in the Los Angeles harbor, where they are transferred into several special ships that make regular runs to company export terminals at Rotterdam, Nules (Spain), and Singapore. Unit trains are also used to supply major customers in the United States. Smaller shipments are packed in 2,000-lb super sacks or in special bags that are then plastic-wrapped on pallets for distribution by truck or rail. Searles Valley Minerals ships by rail from its plant at Trona.

Table 5. Typical prices per metric ton (May 2005)

Product	Price, US\$
Bulk, f.o.b.* California	
Anhydrous borax (AB)	840-900
Pentahydrate, refined (5 mol)	400-430
Decahydrate, technical (10 mol)	340-380
Boric acid, technical (BA)	900-925
Lump colemanite, Turkey, f.o.b. U.S./Japan	270-290
Ulexite, f.o.b. Lima, Peru	250-300

Adapted from *Mineral PriceWatch* 2005.

* f.o.b. = free on board.

Turkish and South American imports enter the United States principally through the ports of Charleston, South Carolina, and Houston, Texas.

Other

In Europe, barges are used for distribution to most of the major consumers that receive their borates from the port of Rotterdam. Shipments from Spain move by rail and truck in both bag and bulk. South American shipments are usually made in bags, some of which move by rail, but most shipments are by truckload lots. Most of the Asian distribution of refined borates is bagged, and much of it is railed in open hopper cars.

ECONOMIC FACTORS

Borates are an essential ingredient in many products and are treated as a commodity. Supply and demand have kept prices stable for most major consumers for the past 10 years. Several years ago, U.S. Borax and some other companies decided to exit the consumer market and concentrate on selling to other large manufacturing companies. Although small boxes of Borax 10-mol still appear on supermarket shelves, usage is small and the market shrinking. Bulk shipments and consumer-driven specifications have tailored the current market to major corporations who utilize borates in their end products. In many cases, borates lower the temperature of manufacturing (of, for example, glass, glass-fiber, and enamels) and thus offset a portion of their cost with energy savings.

GOVERNMENT REGULATIONS

Sodium borates on federal lands are currently covered under the provisions of the Mineral Leasing acts of 1917 and 1920. Much of Searles Lake consists of alternating federal sections that are covered under these regulations, as is much of the prospective area of the Mojave Desert. Borate minerals have a 14% depletion allowance. A portion of the Mojave Desert is listed as prime habitat for the desert tortoise (*Xerobates agassizii*), a threatened species. U.S. Borax has purchased more than 5,000 acres near their Boron operation as mitigation for loss of tortoise habitat.

Although there are no reported cases of borate toxicity, a permissible exposure limit (PEL) of 10 mg/m³ of sodium borate dust has been adopted by the Occupational Safety and Health Administration (OSHA). No cases of industrial intoxication or exposure to inorganic borates have been reported. Ingested boric acid is excreted rapidly, and there is no evidence of carcinogenic or mutagenic activity (Smith and McBroom 1992).

OUTLOOK FOR THE FUTURE

Borates currently have a vital role in producing glass fibers and heat-resistant glass by reducing energy costs and improving

strength. Both of these markets are relatively new and are projected to continue well into the future. Continued development of specialty fertilizers containing borates, targeted to specific agricultural crops, is increasing, as is the use of zinc borates in flame and fire retardants in plastics and wiring. Treating wood products to prevent termite damage is also an important and continuing use. Boron-fiber-reinforced plastics are finding increased roles in the construction of parts for air and spacecraft, automobiles, and military uses.

Soaps and detergent use is decreasing in total volume, especially in Europe, although special beauty aids continue to be an important niche market. Fiberglass insulation has gone through a cycle of borate use and reduction but remains a major end product. Boron-nitride coatings find use in cutting tools and grinding processes and in special technologies where resistance to wear and high heat are important considerations. Boron carbide control rods remain the major controlling devices for nuclear reactors. Minor but important uses are in the encasement of spent nuclear waste, special optical fibers, high-gloss paints for the auto industry, and high-intensity electromagnets.

To reduce chemical waste, U.S. Borax has introduced a borate autocauticizing process into the kraft paper industry. A possible major new use is in automotive fuel cells using sodium borohydride, which is recyclable. Many electronic items use liquid crystal displays that require minute amounts of boric oxide, again, a niche market that only borates can fill. Research continues into boron esters and polymer substances, with many potential new uses in the field of superconductors and electrolytes. Medical research into the use of borates shows promise in cancer treatment where borates target cancer cells for absorption of thermal neutrons (called BNCT, or boron neutron capture therapy).

Bromine

Ron Frim and Shmuel D. Ukeles

INTRODUCTION

Bromine, a heavy, mobile, reddish-brown liquid with an intensely irritating odor, is the only non-metallic element that is a liquid at normal room temperatures. Bromine belongs to Group 17 (VIIA)—the halogen group of elements—in the periodic table. It is a diatomic molecule with the chemical formula Br_2 . Its place in the periodic table is between chlorine (a gas) and iodine (a solid). The atomic number of the bromine atom is 35 and its atomic weight is 79.904. Within wide limits, both the liquid and vapor are diatomic (Br_2).

Carl Lowig, a young chemistry student, originally prepared bromine the summer before beginning his first year at the University of Heidelberg. Winter exams and holidays delayed the continuation of his work long enough for another chemist, Antoine Jerome Balard, to publish a paper in 1826 describing the new element that he had discovered in seawater bitterns. Balard was thus credited with the discovery of bromine, and the French Academy of Science named it after the Greek *bromos*, meaning stench.

The first commercial production of bromine in the United States was from salt brines in 1846 at Freeport, Pennsylvania. In Germany, the first commercial production plant began operation in 1865. This German plant used solutions from the Stassfurt potash factories in its bromine production. Contrary to the method used by Balard to obtain bromine—oxidizing the bromide ion with chlorine—the German process was based on oxidation using manganese dioxide with the aid of sulfuric acid.

Bromine, which occurs naturally in sea water and brines, is extracted using a number of processes. Herbert Dow invented the *blowing out* process for use on Midland (Michigan) brines in 1889. A very small plant in Canton, Ohio, and then a second plant only a little bigger than the first used the blowing out process. Brine electrolysis liberated bromine for a certain period, and then was replaced by the use of chlorine to reduce the bromide to bromine.

Bromine has a number of industrial uses including in flame retardants, drilling fluids, agricultural chemicals, and water treatment.

PRODUCTION AND TRADE

World bromine production capacity in 2003 was estimated to be >563,000 t (Lyday 2003). Two countries and three companies maintain most of this production capacity: the United States (Albemarle Corporation and Great Lakes Chemical Corporation) and Israel (Dead Sea Bromine Group). Of the almost 548,000 t of bromine produced in 2002, the United States accounted for approximately

39% of this amount and Israel accounted for 38%. The three companies also accounted for the majority of the world trade in bromine derivatives.

Principal Producing Countries

China

Official figures indicate that China produces an estimated 40,000 tpy of bromine. This is believed to be a conservative estimate: the Ocean Chemicals Group (OCG) is reported to have a production capacity of 50,000 tpy at facilities north of Laizhou Bay.

Commonwealth of Independent States (CIS)

The U.S. Geological Survey (USGS) estimates that Azerbaijan produced about 2,000 t of bromine in 2002; Ukraine produced about 3,000 tpy; and Russia produced about 3,000 tpy. Kazakhstan and Turkmenistan apparently hold considerable promise for future production based on brines associated with massive natural gas reserves.

France

Overall production estimated for France in 2001 and 2002 was 2,000 tpy. This production rate has been constant since 1996. Elf Atochem SA produces this amount of bromine in southeastern France in its Port-de-Bouc plant, which has a capacity of 12,000 t. The company is investing about \$12.8 million in a specialty brominated derivatives plant based on the bromine from the Port-de-Bouc plant. The derivatives production is destined for the pharmaceutical industry. Albemarle Corporation operates a flame retardant plant at Port-de-Bouc in addition to a bromine derivatives plant at Thann.

India

Although no detailed production figures were found for India, the little information available indicated production levels of about 1,500 tpy, produced from salt production bitterns. Solaris Chemtech Ltd. (formerly BILT Chemicals, Gujarat) is planning to expand yearly production to 10,000 t in the near future.

Israel

Dead Sea Bromine Group (DSBG) produces bromine and bromine derivatives for applications in air conditioning, batteries, cleaning solvents, flame retardants, mineral separation, oil-well drilling, photography, and water treatment. From 1998 through 2002, more

* Estimated numbers.

† Revised numbers.

than 90% of its sales were from exports. Table 1 shows production figures for DSBG during that time period (Yager 2002).

Japan

The Tosoh Corporation, Japan's largest bromine producer, extracts bromine from sea water. It has a reported production capacity of 24,000 tpy (Davenport 2003).

Jordan

The bromine production capacity of the recently constructed Jordan Bromine Company plant at Safi is 50,000 tpy. The plant also produces 35,000 t of calcium bromide and 50,000 t of tetrabromobisphenol for Asian and European markets.

United Kingdom

Until the end of 2003, when the Great Lakes Chemical Corporation closed its plant at Amlwch, Wales, about 28,000 tpy of bromine was extracted from seawater in the United Kingdom.

United States

Current U.S. production of bromine is from inland brines, which are in plentiful supply. The most concentrated domestic brines (up to 5,000 ppm bromide) are in Arkansas and less-concentrated brines (about 2,500 ppm bromide) are in Michigan. An advantage of the Arkansas brines is that they come to the surface at approximately 96°C, a temperature favorable for bromine extraction.

According to USGS data, the quantity of bromine sold or used in the United States from three companies operating in Arkansas and Michigan was equal to production and had a value of \$155 million in 2002. In 2003, the estimated U.S. bromine production was 216,000 t; in 2002 production was 222,000 t (Lyday 2004).

The apparent consumption of bromine in the United States during 2002 was 216,000 t, an increase from 214,000 t in 2001 (Lyday 2004). The estimated bromine consumption for 2003 was 211,000 t. U.S. bromine usage is divided into the following categories and percentages: fire retardants (40%); drilling fluids (24%); brominated pesticides (12%); biocides/water treatment chemicals (7%); and other products (17%). The other products are photographic chemicals, rubber additives, dyes, pharmaceuticals, brominated intermediates (used to manufacture products and bromide solutions used alone or in combination), and gasoline additives. The brominated gasoline additives and halon markets have virtually disappeared because of environmental considerations and legislation. Unofficial sources predict that other markets will show either modest growth or decline in the coming years, except for water treatment applications, which should demonstrate good growth.

Overall, demand for bromine in the United States was estimated to grow at a modest yearly rate of about 1% to 2% from 2001 through 2006. This estimate was based on the assumption that no new, major legislative restrictions would be placed on bromine chemical use during that period.

The USGS maintains bromine production data. The apparent consumption of elemental bromine in the United States has been defined as production plus imports minus exports. Table 2 gives the

Table 2. U.S. supply and demand data for elemental bromine, 1995–2004, kt*

Year	Annual Capacity	Production	Imports	Exports	Apparent Consumption

supply and demand data for elemental bromine from 1995 through 2002, and estimates for 2003 and 2004.

Most bromine trade involves bromine derivatives rather than elemental bromine. The United States imports a wide range of bromine-containing chemicals, including bromide salts such as ammonium bromide, calcium bromide, potassium bromide, and sodium bromide, as well as sodium bromate and potassium bromate. Other imported bromine chemicals were mainly organics, largely brominated fire retardants from Israel. Table 3 lists U.S. imports of bromine chemicals for 1995 through 2003.

Exports of bromine chemicals from the United States to other countries have been estimated to be about 49,000 to 51,000 t (gross weight). The major portion of this quantity was flame retardants, estimated to be about 30,000 t.

Principal Producing Companies

Albemarle Corporation

The Albemarle Corporation, headquartered in Richmond, Virginia, was spun off as a separate company from the Ethyl Corporation in 1994. The company has two operating divisions: the Fine Chemicals Division, which produces performance chemicals, pharmaceuticals, and agricultural products; and the Polymer Chemicals Division, which produces fire retardants (brominated and non-brominated), catalysts, and adhesives. Total annual sales of about

† CIS here includes Azerbaijan, Turkmenistan, and Ukraine.

‡ Estimated figures.

\$980 million have been reported. Bromine is critical to many of the company's products. Aside from manufacturing brominated fire retardants, Albemarle also produces other products containing bromine, including metal alkyls, inorganic bromides, and a number of fine chemicals. Albemarle's bromine-based operations are in the United States and France. In 1999, Albemarle Holdings (an Albemarle affiliate) established a joint venture with Arab Potash/Jordan Dead Sea Industries to construct a bromine and bromine derivatives complex at Safi, Jordan, on the Dead Sea. Phase one, which opened in October 2002, was a bromine unit and a production facility for inorganic bromides and hydrogen bromide. The second phase involves the construction of a Sayytex CP-2000 (tetrabromobisphenol) flame-retardant plant.

Dead Sea Bromine Group

DSBG, headquartered in Beer Sheva, Israel, is the world's largest producer of elemental bromine. Total annual sales are more than \$500 million (Y. Gramse, personal communication). The company's elemental bromine plant is on the shore of the Dead Sea, and an affiliated company, Dead Sea Works (a producer of potash and other inorganic chemicals), supplies the raw material for its bromine production. Israel Chemicals, which has its headquarters in Tel Aviv, owns both companies. DSBG—through subsidiaries such as Bromine Compounds (Ramat Hovav, Israel)—produces a broad range of organic and inorganic bromine compounds.

In addition to elemental bromine and bromine derivatives in Israel, DSBG also produces bromine derivatives in the Netherlands at its Eurobrom facility. DSBG and its subsidiaries are grouped into eight business units that produce elemental bromine, flame retardants, biocides, agrochemicals, oil-field chemicals, industrial chemicals, organic intermediates, and fine chemicals.

In 2003, DSBG and Manac of Japan signed an agreement for long-term cooperation to produce and market a flame retardant for engineering plastics. Also in 2003, DSBG entered into a long-term strategic sourcing agreement for elemental bromine and certain bromine derivatives with the Great Lakes Chemical Corporation.

Great Lakes Chemical Corporation

Great Lakes Chemical Corporation (GLCC), with headquarters in Indianapolis, Indiana, has total yearly sales of more than \$1.5 billion. It has four operating units: water treatment, polymer additives, performance chemicals, and energy services and products. All these units generate bromine-containing products. The polymer additives unit produces flame retardants and polymer stabilizers. The flame retardant segment uses brominated and nonbrominated compounds.

The performance chemicals unit uses elemental bromine, methyl bromide, and other bromine products. GLCC's elemental bromine production is primarily from brines in Arkansas, but it also operates a plant in the United Kingdom (Associated Octel) that extracts bromine from seawater.

Brominated compound production, especially flame retardants, is focused in the United States, but there is also production in the United Kingdom. GLCC has formed a joint venture for tetrabromobisphenol with DSBG at Ramat Hovav, Israel. In 2003, GLCC and the ICL Industrial Products Division (Israel) announced a global agreement whereby the latter would supply bromine and bromine compounds to GLCC.

World Production Statistics

In 2002, the United States continued to maintain its leading position in bromine production, which was estimated at about 222,000 t that year. Israel was second with 206,000 t. These two countries accounted for about 78% of the world's elemental bromine production of 550,000 tpy. Other leading producers accounted for the remaining 22%, including China, France, India, Japan, the United Kingdom, and CIS members.

Table 4 gives production data for the world's largest producers of bromine for 1995–2003. Harben (2003) presented slightly different figures that reflect data not available through USGS.

OCCURRENCE

Distribution in Nature

Bromine is distributed widely in nature as bromide salts and as organobromine compounds, which are produced by various marine organisms. Bromine is present in the hydrosphere, mainly as soluble bromide salts in seawater, salt lakes, inland seas, natural brine wells, and in evaporite chloride minerals. Concentrations vary from 65 mg/L in seawater up to 6.5 g/L in the southern basin of the Dead Sea. Its abundance in igneous rocks is 0.00016% by weight, whereas seawater has an abundance of 0.0065% by weight.

The only minerals that contain bromine are some silver halide ores: bromyrite (AgBr), embolite [Ag(Cl, Br)], and iodobromite [Ag(Cl, Br, I)]. H.E. Boeke (1908) determined the distribution of bromine in marine evaporite minerals, and in the solutions from which they crystallize.

Terrestrial plants contain an average of about 7 ppm bromine. The highest bromine content in animal life is found in marine animals (e.g., fish, sponges) and crustaceans. Animal tissues contain 1 to 9 ppm bromide whereas animal blood has a content of 5 to 15 ppm bromine.

Figure 1. Mutual solubility of bromine and water

Commercial Sources and Reserves

The Dead Sea is today the richest commercial source of bromine; its brines contain 5 g/L bromine in the open sea, 6.5 g/L in the southern basin (near Ein Bokek, Israel), and up to 12 g/L in the end brine from potash production. This end brine serves as an almost unlimited source of raw material for Israeli and Jordanian bromine production. Other important bromine sources are underground brines in Arkansas (3 to 5 g/L) and Michigan (2 to 3 g/L) (United States), Russia, China, and the United Kingdom; bitters from mined potash (France and Germany); and sea water or sea water bitters in France, India, Italy, Japan, and Spain.

Table 5 gives a breakdown of the estimated world bromine reserves by country (Lyday 2005). The Dead Sea is estimated to contain about 1 billion t of bromine. The bromine content of underground brines in Poland has been estimated at 36 Mt.

Analytical Methods for Bromine and Bromides

The analysis for liquid bromine and bromine is based on its reaction with an aqueous potassium iodide solution to form molecular iodine, followed by its titration with a standard sodium thiosulfate solution. Bromine vapor can also be determined by absorption into aqueous potassium iodide solution and subsequent iodometric titration of the liberated iodine. Impurities in bromine (e.g., chloride, iodide, sulfur, water, organic compounds, and heavy metals) can be determined quantitatively.

Other methods for determining bromine are the Mohr, Volhard, and Fajans methods, silver nitrate titration using a silver indicator electrode, and a gravimetric method (silver bromide). Some methods used for determining trace amounts of bromide quantitatively are

- the van der Meulen method, which is useful in the presence of large chloride concentrations;
- constant-current and constant-potential coulometry, which can determine fractions of a milligram to several grams of bromide;
- ion chromatography;
- polarography for microgram quantities; and
- a spectrophotometric method, which is useful for microgram quantities in the presence of chloride.

Bromine in organic compounds can be determined by chemical methods following their oxidation and the reduction of bromine to bromides. The bromine content in the organic compounds can be determined subsequently by one of the following methods: neutron activation, x-ray fluorescence (XRF), infrared spectroscopy, or atomic emission spectroscopy.

PROPERTIES OF BROMINE

Physical Properties

Bromine liquid volatilizes readily at room temperature into reddish vapor, which is highly corrosive to many materials and human tissues. The liquid and vapor are diatomic (Br_2) up to about 600°C. Table 6 gives some of bromine's most important physical properties (Grinbaum and Freiberg 2002).

Bromine is fairly soluble in water, having the following solubilities at the corresponding temperatures: 3.41 g/100 g solution at 20°C; 3.35 g/100 g solution at 25°C; and 3.33 g/100 g solution at 40°C. The solubility of bromine increases in the presence of bromide or chloride ions from complex ion formation (e.g., formation of tribromides and pentabromides). Bromine is also soluble in nonpolar solvents (e.g., carbon tetrachloride, chloroform, carbon disulfide, and ether) and polar solvents such as methyl alcohol and sulfuric acid. Figure 1 shows the mutual miscibility of bromine and water.

Chemical Properties

Bromine, as other halogens, has a tendency to accept an electron to form either a negative bromide ion (Br^-) or a single covalent bond ($-\text{Br}$). Except for helium and neon, the other elements of the periodic table are able to form halides with the halogens, including bromine. The bromides that are primarily ionic in nature tend to have high conductivities in the fused state and high boiling points, and are not susceptible to hydrolysis if they are soluble bromides. The predominantly covalent bromides that can form are volatile and nonconductive in the liquid state, and usually undergo hydrolysis. The nonmetallic bromides generally hydrolyze to hydrogen bromide and an oxy-acid containing the other element.

Reactions with Hydrogen and Metals

Bromine reacts with hydrogen at elevated temperatures to form hydrogen bromide. Heated charcoal and finely divided platinum

metal are used as catalysts for this reaction, which is the basis for the commercial production of hydrogen bromide. Bromine reacts with all metals except tantalum and niobium; elevated temperatures are sometimes necessary to accomplish this conversion. The reaction of bromine with lead, magnesium, nickel, and silver forms a surface coat of bromide that resists further attack. This protective coating permits the use of lead and silver as linings in bromine containers. Metals corrode more rapidly from bromine in the presence of moisture than in its absence, probably because of the formation of hydrobromic acid (HBr) and hypobromous acid (HOBr).

Reactions in Water

When bromine dissolves in water, it undergoes partial disproportionation to form hypobromous acid, hydrogen ions, and bromide ions. The hypobromous acid is relatively stable only in solution and decomposes under the influence of heat, light, or copper catalysis to produce HBr and oxygen. In the dark, hypobromous acid decomposes to bromic acid (HBrO_3) and bromine. Bromic acid is relatively unstable and slowly decomposes to form bromine and oxygen (Grinbaum and Freiberg 2002).

In basic solution, bromine reacts rapidly to form bromide (Br^-) and hypobromite (OBr^-) ions. It is necessary to maintain this reaction below 0°C to limit the disproportionation of hypobromite to bromate and bromide.

Reactions with Organic Compounds

Bromine can react with organic compounds in various ways (Ioffe and Kampf 2001). Typical of such reactions are the addition of bromine to unsaturated hydrocarbons and the substitution of hydrogen on an organic substrate, with corresponding release of hydrogen bromide. It is possible to carry out reactions both in the liquid or vapor phases and in the presence or absence of solvents or catalysts. Some of the solvents used are chloroform, carbon tetrachloride, acetic acid, and hydrobromic acid. Lewis acid catalysts (e.g., aluminum chloride) are used frequently for the bromination of aromatic compounds, whereas light or peroxide catalysts are used in the bromination of aliphatic compounds.

The indirect reaction of other functional groups with bromine derivatives is the preferred method for the preparation of some organic compounds. An example is the preparation of methyl bromide (an alkyl bromide), which is best prepared by the reaction between methanol and hydrogen bromide. An alternate preparation of alkyl bromides is by the reaction of hydrobromic acid to an olefinic compound.

TECHNOLOGY

Processing Methods

Current methods for bromine production use chlorine to oxidize bromide to bromine. The principal processing steps follow:

1. Oxidize bromide to bromine.
2. Strip bromine from the aqueous solution.
3. Separate the bromine from the resulting vapor.
4. Purify the bromine.

Differences between various processes generally are manifested in the stripping and purification steps.

The two principal processing variations are the *steaming-out process* and the *blowing-out process*.

Steaming-Out Process

The current process used for producing bromine from bromide-containing brines (1 to 5 g/L Br^-) is based on the *hot* or *steaming-out* process first described by Konrad Kubierschky in 1906 (Jolles

1966). It consists of simultaneous chlorination and steam blowing. The brine is preheated, usually to $75^\circ\text{--}80^\circ\text{C}$, before its introduction into the Kubierschky tower, and then heated inside the tower by live steam to near boiling. The bromine is steam-distilled as it is being set free by the chlorine. The distillation steam is a small fraction of the live steam supplied to heat the brine. The steaming-out process requires heating the brine to near boiling and reducing the partial pressure of bromine (and chlorobromide) in the effluent brine to nearly zero to improve the stripping of the bromine from the brine. Drying the brine usually is achieved with sulfuric acid.

The advantage in the steaming-out process is that bromine is condensed directly from the steam, as opposed to the air blowing-out process, in which the bromine is trapped in an alkaline or reducing solution to concentrate it.

Blowing-Out Process

The blowing-out process uses air rather than steam. (The cost of steam to heat ocean water, with its very low bromine content of 65 mg/L, is prohibitively expensive.) In this process, bromide-containing water is pumped to the top of blowing-out towers. Sulfuric acid and chlorine are added above the pumps to ensure that mixing occurs in the brine during its ascent. An excess of about 15% chlorine is used over the theoretical amount required. Air is drawn through the towers, thus sweeping out a mixture of bromine and chlorine (or bromine chloride) from the descending water. The bromine-laden air is drawn next through the absorber towers in which it is scrubbed countercurrently with a sodium carbonate solution. To remove the spray from the air, small packed chambers are interposed between the absorber towers and the fans. When the alkalinity of the scrubber solution is nearly depleted, the solution is transferred to a storage tank and then to a reactor where it is treated with sulfuric acid and steamed to release bromine. Subsequently, the bromine is condensed.

Production from Wastes

An increasing amount of bromine is being produced from wastes. Hydrogen bromide, which is emitted as a by-product in many organic reactions, is a major source for this kind of bromine production. Part of the hydrogen bromide comes from incinerating organic wastes in a bromine recovery unit (BRU). The emitted flue gases from the BRU contain hydrogen bromide and molecular bromine, which are usually separated before the hydrogen bromide processing. The process used to recover bromine is similar to that used for producing bromine from bromides, that is, by oxidation with chlorine gas or another oxidant.

Another approach tested recently is recovering bromine from hydrogen bromide waste streams using electrolytic membranes to decompose the hydrogen and bromine. This process apparently has not yet been commercialized.

Product Specifications

Table 7 lists the American Chemical Society (ACS) specifications for reagent grade bromine and typical product specifications for purified bromine. The bromine content (by weight %) represents a minimum value, whereas the water and chlorine contents are maximum values (Grinbaum and Freiberg 2002).

MARKETS

Uses of Bromine

The synthesis of a wide range of brominated organic compounds involves the direct or indirect consumption of bromine. For the majority of brominated flame retardants (BFRs), bromine reacts with a suitable starting material to form the flame retardant (FR) along with one molecule of hydrobromic acid for each atom of

Table 7. Specifications for elemental bromine

Parameter	ACS Specification	Product Specification
Bromine content, %	99.5	99.9
Specific gravity, 20/15°C	na*	3.1
Water, ppm	na	30
Chlorine, ppm	500	100
Organic halogen compounds, ppm	Must pass ACS test	80
Nonvolatile matter, ppm	50	30
Iodine, ppm	10	Must pass ACS test
Sulfur (as S), ppm	10	Must pass ACS test
Heavy metals (as Pb), ppm	2	Must pass ACS test
Nickel, ppm	5	Must pass ACS test

* na = not available.

bromine contained in the end product. The hydrobromic acid produced is further reacted (e.g., with an alcohol to form an alkyl bromide) or neutralized to form a bromide salt.

Before describing uses, a few words should be devoted to the use of bromine in ethylene dibromide (EDB) as a gasoline additive. Bromine demand for this use steadily declined each year after the U.S. Environmental Protection Agency (EPA) issued regulations in the 1970s to reduce and eliminate lead in gasolines. (The EDB acts as a lead scavenger by converting lead oxides to lead bromide, which then escapes along with the engine exhaust.) An EPA mandate to eliminate all the lead from motor vehicle gasoline formulation by 1996, therefore, decreased EDB consumption drastically. Some lead is still used in aviation fuel formulations, although most of the small amount of U.S. production is exported to countries still having less-strict environmental legislation.

Flame Retardants

BFRs are still a growing market. The total global FR market has an estimated annual volume of approximately 2.0 billion lb (about 909,000 t), valued at about \$2.2 billion. Halogenated materials, which include halogenated phosphorous FRs, make up about 35% to 40% of this volume and are 55% by value. BFRs alone account for 25% of the volume and 35% of the value (Tullo 2003). Brominated polymers are used in FR applications and bromine-containing epoxy sealants are used as FRs in semiconductor devices.

The BFRs (which are typically brominated aromatic or cyclic aliphatic compounds), can be the additive type, where the FRs are incorporated as a constituent in mixtures with polymers before, during, or more likely after polymerization; or the reactive type, where the FR is bonded chemically to the polymer itself. The BFR slows down or stops flame generation in polymer systems by interfering with the chain reaction mechanism of combustion, that is, by extinguishing radicals that serve to propagate oxidation. Synergists such as antimony trioxide, antimony pentoxide, or zinc borate add to the effectiveness of BFRs as do halogens when they are present in the polymer.

The consumption of bromine in FRs has risen steadily over the last several decades, mostly because of increased use of electronics and communications products. Because of the significant economic downturn in 2001, however, consumption fell drastically to its lowest level in many years.

Drilling Fluids

The oil and gas drilling industry uses calcium, zinc, and sodium bromides to prepare high-density, clear drilling, completion, packer,

and workover fluids (Ukeles and Freiberg 2002). These brine fluids are used in deep, high-pressure oil and gas wells; they do not plug the formation in workover and completion operations, as conventional drilling muds can do. Such bromide salt brine usage has led to higher production rates and longer production lifetimes. For such applications, calcium bromide is the largest volume bromide salt in use, followed closely by zinc bromide and sodium bromide. Sodium bromide finds use in specialized situations where calcium or zinc brines could cause a minimal amount of swelling, or in carbon dioxide-containing strata where there is a danger of calcium carbonate precipitation.

The bromine-based completion fluids are used in both of offshore and onshore drilling operations. Recent expansion in drilling activity and in the type of activity—namely deep, high-pressure wells—has contributed to the rapid growth of this market.

The inorganic bromides used in this application are prepared by neutralizing hydrobromic acid, which represents one of the two largest uses for this acid.

Brominated Agricultural Chemicals

Methyl bromide is currently the major bromine-containing pesticide used worldwide, but its use is declining. It is a broad-spectrum pesticide used to control pest insects, nematodes, weeds, pathogens, and rodents. About 25,000 t of methyl bromide were produced in the United States in 1999 for both domestic and foreign markets; much of it was produced as a by-product of BFR manufacture. Applications include soil fumigation, commodity and quarantine treatment, and structural fumigation. Global production in 1999 was estimated to be about 52,000 t.

When used as a soil fumigant, methyl bromide usually is injected into the soil at a depth of 30 to 60 cm before a crop is planted. This effectively sterilizes the soil, killing most soil organisms. After injection, the soil is covered with a tarp for 24 to 72 hr to slow the movement of methyl bromide from the soil to the atmosphere.

The three major manufacturers of methyl bromide—Albemarle Corp., GLCC, and Israel's DSBG—account for 75% of global production.

Biocides/Water Treatment

Even with continued dominance of chlorine in most of the water treatment sector, brominated compounds continue to make inroads into that market. This is probably due in part to environmental restrictions that chlorine has experienced in recent years. Among the advantages that bromine enjoys over chlorine in some water treatment areas are the following:

- Brominated compounds are less likely to form undesirable, halogenated organic compounds.
- Bromine has been found to be more efficient at higher temperatures than unstabilized chlorine.
- Brominated compounds are more effective at lower concentrations and at a higher pH than chlorine, thus allowing for greater throughput in waste treatment plants and cooling towers.
- Debromination of treated effluent streams is unnecessary, and any bromamines that are formed degrade more rapidly than the corresponding chloramines.
- Brominated products are estimated to be three times more effective than chlorine at controlling algae in cooling towers.

Bromine (e.g., bromochlorodimethylhydantoin [BCDMH]) has also made gains in the consumer water conditioning market as a

biocide for spas, pools, and hot tubs. The brominated hydantoin releases both hypochlorous and hypobromous acid in solution, where the latter is more effective at higher pH.

Brominated Intermediate

Brominated compounds are frequently used as intermediates in the production of other organic chemicals such as agrochemicals, pharmaceuticals, and dyes. For such applications, no bromine is present in the end product. Some of the bromine released during production processes that use these intermediates may be recovered and recycled (generally as hydrobromic acid or as a bromide salt); there are losses, however, that result when the by-product becomes too dilute or too contaminated. Some examples of chemicals that are used as intermediates are bromoacetyl bromide (cefotetan, labetalol), n-hexyl bromide (a building block for fragrances and dyes), 4-bromoaniline (meto bromoron, resorantel), and 2-bromopropionic acid (naproxene, prilocaine).

Other Uses

A number of pharmaceuticals are prepared in the form of bromides or hydrobromides. One example is the antitussive (alleviates or prevents coughs) dextromethorphan hydrobromide. Bromide salts also find use in some rechargeable batteries.

More than 5,000 t of bromine are used in the United States in the production of bromobutyl rubber for the inner linings of automobile tires. The majority of tire manufacturers prefer the improved performance of the bromine derivative over the chlorine-containing compound (i.e., chlorobutyl rubber).

Bromine is capable of desulfurizing fine coal (Grinbaum and Freiberg 2002). Bromine and its salts are known to recover gold and other precious metals from their ores by serving as an oxidant and complexant of gold.

Zinc-bromine storage batteries are being developed as load-leveling devices for use in electric utilities. In addition, photovoltaic batteries have been made from selenium or boron doped with bromine. Bromine also is used in quartz-halide light bulbs.

Product Pricing

Data from USGS indicated that the average price of purified elemental bromine was 99 cents/kg (44 cents/lb) during 2002. This was an increase from 67 cents/kg (30 cents/lb) for 2001. The price cited for 2001 represents a sharp decrease from the 2000 price, which was listed as 90 cents/kg (41 cents/lb) (Davenport 2003). According to Lyday (2005), prices peaked again in 2002 at 99.2 cents/kg (45.1 cents/kg) before declining to 72.0 and 70.0 cents/kg (32.7 and 31.8 cents/lb) in 2003 and 2004, respectively.

Packaging

Bromine is generally supplied as a liquid in drums or portable tanks (isotanks), depending on the quantities required by the customer. Hazardous Materials Regulations (HMR) are based on the recommendations of the United Nations Economic Commission for Europe (UNECE; 2005). Known as the "Orange Book," the UNECE directory provides an extensive list of dangerous goods and their control in transport by air, rail, road, sea, and inland waterways. It covers classifications and definitions of all dangerous substances; packaging, labeling and relevant shipping documentation; and training of transport workers.

In the United States, bulk quantities of bromine are shipped in lead-lined pressure tank cars or nickel-clad pressure tank trailers (filled to 92% of capacity). International shipments made by DSBG are in 15.2 to 23.3 t (5,300 to 8,000 L) lead-lined tank containers (isotanks). For smaller quantities of bromine, lead-lined

tanks ("goslars") of 3.5 t (4 t packed on one isoframe) and 400-kg (140-L) drums are used. Packaging is designed according to UN recommendations for Packing Group I.

Problems may be encountered in shipping and storage because of the relatively high freezing point of bromine (i.e., -7.25°C). If bromine freezes in a tank car, warm water—below 54°C —must be circulated through the car's heating coils.

Engineering Materials

Because bromine is highly hygroscopic, improper handling may cause its water content to increase to >300 ppm. When water content and organic matter content of bromine increase, the probability that it will corrode engineering materials increases. Therefore, bromine must be stored under dry nitrogen or dry air. Bromine with <30 ppm water content is noncorrosive to many nonferrous metals, including lead, nickel, tantalum, Hastelloy B, Hastelloy C, and Monel.

Some of the points previously mentioned are amplified below:

- Lead and lead-lined steel are commonly used in process equipment and storage containers when bromine is dry. The protective layer of lead bromide formed on the interior of a storage vessel allows it to be used with bromine with a water content up to 75 ppm.
- Glass has excellent resistance to wet or dry bromine corrosion.
- Nickel and nickel alloys such as Monel 400 and Hastelloys B and C are corrosion resistant to dry bromine (<30 ppm water) but are attacked rapidly by wet bromine.
- Tantalum and niobium both have excellent resistance to corrosion to either wet or dry bromine and can be used at temperatures up to 149°C .
- Steel and stainless steel are not recommended as construction materials because of corrosive bromine and bromine vapors.
- Fluorinated plastics such as Kynar, Kalrez, Halar, and Teflon (polyvinylidene fluoride [PVDF], perfluoroelastomer parts, ethylene-chlorotrifluoroethylene [ECTFE], and polytetrafluoroethylene [PTFE], respectively) are resistant to bromine corrosion and are used in valves, piping, gaskets, and linings.
- It is not recommended to use other types of polymers if contact with bromine is imminent.

Storage

Bromine for laboratory or pilot use generally is purchased in glass bottles. It is poured or pumped into small glass, ceramic, or lead-lined vessels that are equipped with PTFE stopcocks. The bottles are stored in their cartons in a dry, cool location away from direct sunlight. The storage temperature should not fall below the freezing point of bromine, -7°C .

Drum, tank truck, or carload quantities of bromine are stored in lead, lead-lined steel, or glass-lined steel storage tanks, which feed into a particular process or reaction. When using larger storage tanks (where bottom outlets cannot be used), the bromine should be pumped out of the tank with nickel, PVDF, or PTFE pumps.

Drums should be stored empty or full in an upright position, in a cool (above -7°C), dry place. Exposure to heat will cause a dangerous pressure buildup to develop. Protection from moisture and humidity is extremely important. GLCC offers bromine in non-returnable 120-gal steel cylinders that hold about 2,800 lb of bromine. The precautions previously outlined for drum storage also apply to cylinders.

Storage tanks also should be protected from moisture or humid air, because bromine will absorb moisture. When bromine is exposed to air having a normal summer dewpoint of 5° to 10°C , it

will equilibrate with about 70 to 80 ppm water. Wet bromine can severely corrode many metals. A slight positive pressure (0.1 in. of water) should be maintained in storage tanks by purging with dry air or dry nitrogen.

Transport of Bromine

A number of options are available for the transport of bromine. For example, GLCC ships bromine in bulk, using lead-lined, double-barrel tank trailers with a capacity of about 600 gal. Another option offered by GLCC is bromine in bulk either in 2,400 gal (56,000 lb) or in 4,400 gal (110,000 lb) lead-lined tank cars. The liquid bromine supply configurations used by DSBG (e.g., drums, goslars, or isotanks) were previously described.

Because bromine is a very corrosive and toxic material, regulations mandate which materials can be placed in proximity with, or require separation from, bromine. These regulations are available in the International Maritime Dangerous Goods (IMDG) code that covers regulations for international shipping.

U.S. Department of Transportation (DOT) regulations allow the transport of bromine within the United States, although it must be packaged, marked, labeled, placarded, stowed, segregated, and certified in accordance with the IMDG code, provided that part or all transportation is by vessel (Gilmour 1998). The total quantity in one tank may not be less than 88%, or more than 92% of the tank volume.

HEALTH AND SAFETY FACTORS

Effects of Exposure

Bromine has a sharp, penetrating odor. Bromine exposure—by liquid contact or vapor inhalation—is a considerable hazard with potential risk for serious injury and even death (Reineke 1978). The liquid rapidly attacks skin and other tissue to produce irritation and necrosis. Vapor concentrations of about 1 ppm are unpleasant, can cause eyes to water, and are highly irritating to the entire respiratory tract; 10 ppm becomes intolerable, even for more than a few moments.

If 10 ppm or more of toxic bromine are inhaled, severe burns and serious inflammation in the respiratory tract result, and these are frequently followed by pneumonia (Grinbaum and Freiberger 2002). Some symptoms of overexposure include coughing, nosebleed, feeling of oppression, dizziness, headache, and possibly delayed abdominal pain and diarrhea.

Skin contact with liquid bromine produces an initial mild cooling sensation, followed by a heating sensation. If bromine is not removed by washing the area affected with water, the skin will turn red, then brown, and the resulting deep burn is slow to heal. Contact with concentrated bromine also results in burns and blisters. Small areas in the laboratory that have become contaminated with bromine can be neutralized with a 10% solution of sodium thiosulfate. Such a solution should be kept readily available when working with bromine.

Vapor concentrations of 500 to 1,000 ppm by volume are dangerous to life at exposures for 0.5 to 1.0 hr. With respect to respiratory exposure, the Occupational Safety & Health Administration (OSHA) threshold limit value—time weighted average is 0.1 ppm in air for an 8-hr working day and 40-hr workweek. Monitoring devices are available for determining bromine concentrations in air.

Protective Equipment for Bromine Handling

Processes incorporating bromine should use totally enclosed systems. The minimum safety equipment requirements for handling bromine in the laboratory are chemical goggles, rubber gloves

(Buna-N or neoprene rubber), laboratory coat, and fume hood. For handling bromine in a manufacturing plant, personal protective equipment should include hard hat, goggles, neoprene full-coverage slicker, Buna-N or neoprene rubber gloves, and neoprene boots. When evacuating from an area where a release of bromine has occurred, a full-face respirator with an organic vapor-acid gas canister is desirable.

Fire Precautions

In case of fire, personnel should wear a self-contained breathing apparatus when working in an area containing bromine compounds. Bromine does not burn, but it is a strong oxidizer and reacts violently with aluminum, titanium, sodium, and potassium. Wood, paper products, fabric, petroleum products, plastics, and other organics may combust spontaneously in the presence of liquid bromine.

REGULATORY AND ENVIRONMENTAL CONSIDERATIONS

Methyl Bromide

Methyl bromide, which is a known toxic substance to human beings that damages the central nervous and respiratory systems, also may contribute significantly to the destruction of the Earth's stratospheric ozone layer. In September 1997, at the Ninth Meeting of the Parties to the Montreal Protocol, participating members agreed to a schedule for the reduction in the use of this fumigant. In developed countries, most uses were slated to cease in 2005 except for certain exemptions, and developing countries would have until 2015 to phase out methyl bromide.

Methyl bromide was listed as a Class I ozone-depleting substance in the 1990 Clean Air Act Amendments in the United States, which previously had instituted a ban that would take effect in 2001. The U.S. Congress extended the phaseout of methyl bromide to coincide with the 2005 ban set by the Montreal Protocol. To avoid any trade differences that might arise between U.S. growers and those in countries that still would have access to methyl bromide after 2005, the EPA has stated that in the absence of alternatives for methyl bromide, it would support limited, essential uses of this material.

Recently, a UN body (the Technology and Economic Assessment Panel) approved a U.S. request for exemptions from a ban on methyl bromide. This panel recommended exemptions for methyl bromide on U.S. crops such as strawberries, raspberries, eggplant, and tree seedlings. These exemptions have been the focus of objections from the Natural Resources Defense Council.

Flame Retardants

The polybrominated diphenyl ethers (PBDEs) are the BFRs that have been under the most scrutiny because of their apparent persistence in the environment and concerns for bioaccumulation. Recently, GLCC announced a voluntary U.S. phaseout of two PBDEs. The two flame retardants—pentabromodiphenyl ether (penta-BDE) and octabromodiphenyl ether (octa-BDE)—were phased out by the end of 2004 (Hogue 2003). (The phaseout of these two PBDEs is not considered to be as critical as would be any exit from deca-BDE [a styrenics additive], which is produced in the highest volume of the PBDEs.)

Because of environmental regulations, many polymer fabricators are now trying to avoid BFRs altogether. BFR suppliers themselves are diversifying their product offerings to include nonbrominated FRs. Thus, although both Albemarle's and Great Lakes' flame-retardant businesses were 100% bromine-based less than a decade ago, the situation has changed significantly. Through acquisitions and internal developments, roughly 35% of their sales now come from nonbrominated FRs.

OUTLOOK AND FUTURE TRENDS

Unofficial growth estimates for the bromine industry have been placed at about 2% per year throughout 2008. Bromine production from seawater is becoming an expensive process and will eventually become infeasible. No new areas of growth are expected in the near future, so the majority of bromine will continue to be consumed by FRs, intermediates, oil drilling, and biocide applications. The bromine industry has a negative image, which it feels is unjustified. The results from upcoming risk assessments of BFRs (e.g., tetrabromobisphenol A [TBBA], deca-BDE, penta-BDE, and hexabromocyclododecane [HBCD]) will be crucial to the future of the industry. Lobbying activities and industry panels will play an important part in the future of the bromine industry.

The price of elemental bromine and the prices of bromine compounds and derivatives are correlated. The current lower prices of the major brominated products, along with regulatory pressures, threaten the industry's reinvestment capabilities in new R&D and production facilities and thus its long-term viability. In addition, the geographical shift of major industrial chemical activities from the West to China will continue to influence this industry along with others.

China

Approximately 80% of Chinese bromine is produced from saturated brines in Shandong Province (Bohai Bay). The remaining 20% is produced from seawater. Bromine reserves in Shandong are estimated to be 1.0 to 1.5 Mt. Many of the big Chinese producers are also in the process of going downstream to produce brominated compounds, and their relocation to bromine resources is being observed. Also of note is the trend of consolidating smaller bromine plants into one large company. The Chinese bromine industry has the ability to produce new products and improve the quality of existing products (e.g., FRs, dyestuffs, pharmaceuticals, and bromides) rapidly. Many of the bromine industry customers are either producing or in the process of establishing a production base in China. Chinese markets are going to adopt the European regulations (Restrictions of Hazardous Substances, or RoHS) for chemicals such as FRs.

Israel

Of the approximately 548,000 t of global yearly bromine production in 2002, approximately 206,000 t (almost 38% of the total) are produced in Israel. A slightly larger quantity is produced in the United States. The overall estimated global growth of about 2% is also true for Israel. The sole Israeli producer of bromine is DSBG, which is part of the ICL Group. DSBG also produces bromine derivatives that have a wide range of applications. DSBG produces bromine from the Dead Sea, where its concentration ranges between 6.5 g/L in the southern basin and 12 g/L in the liquors remaining after potash production from the Dead Sea.

As previously stated, more than 90% of DSBG's sales are from exports. Therefore the current situation of lower prices for the main brominated products, along with regulatory pressures, threatens the main business of the company and its status as a major producer. DSBG is also a major manufacturer of the fumigant methyl bromide, which is being phased out. Therefore, DSBG, as well as other major producers, are seeking environmentally safe "green" products using bromine and bromine-containing chemicals.

Jordan

Because Jordan is situated on the eastern shores of the Dead Sea, it was only a matter of time before bromine production from Dead Sea brines began. A 25,000-tpy bromine plant was commissioned

in 2003. At full production capacity of 50,000 tpy, this plant would be able to replace the Albemarle production facilities in the United States. The production of brominated compounds (e.g., TBBA) will be able to commence very shortly after that time.

United States

It is difficult to find data on any definitive future demand estimates for bromine in the United States. Unofficial sources have predicted a modest yearly growth rate of about 1% to 2%. This prediction is based on the assumption that no new, major legislative restrictions will be placed on bromine chemical use in the foreseeable future. Bromine production from wells in Arkansas is diminishing at 2% to 3% per year, and higher production costs are anticipated. The major U.S. bromine chemical compounds companies (Albemarle and GLCC) are succeeding in finding alternative bromine sources. Albemarle finalized an agreement with a Jordanian partner to build the bromine plant previously described, with a maximum capacity of 50,000 tpy. GLCC completed an agreement with the Israeli company DSBG for the supply of bromine and brominated products. GLCC is developing alternative flame-retardant products based on tetrabromobenzoate esters as an alternative to the ecologically problematic penta-BDE FR used in the polyurethane sector. Albemarle is enlarging its TBBA (a leading BFR) production capacity. Both companies also have diversified their flame-retardant product lines by moving into nonhalogenated FRs through acquisitions.

OUTLOOK ACCORDING TO MAJOR USE

Flame Retardants

Over the last 10 years, the FR industry has been growing 3% to 5% annually (Chemical Products Synopses 2003). Unofficial figures from reliable sources indicate that the brominated section of the industry is growing at a similar pace. One of the reasons given for continued growth of the brominated segment is the increasingly stringent fire safety standards in place in Europe and the United States as a result of increasing fire-safety awareness. California, the most populous state in the United States, requires fire retardants in polyurethane foam mattresses, and proposed federal laws (e.g., American Home Fire Safety Act) would require similar actions.

Industry observers claim that there are about 50 different major BFRs. All major FRs (e.g., deca-PBDE, HBCD, TBBA, and penta-BDE) are currently undergoing risk assessments to see if they are in accord with the PBT (persistent, bioaccumulation, toxicity) criteria. Increasing efforts are being made to replace these with nonhalogenated FRs or with more environmentally friendly BFRs; that is, reactive ones that will not leach to the environment during use. Thus far, many of the introduced replacements have been different BFRs from the PBDEs that they were to replace. The strategy used by producers of brominated products is to shift from products under attack to products that are considered less environmentally problematic and are recyclable.

Drilling Fluids

The forecast for the clear brine fluids market depends on the general oil and gas drilling business climate, which itself is a highly fluctuating market. The mercurial behavior of this industry is illustrated by the steep decline in drilling activity between 1990 and 1993, followed by a significant increase in activity between 1994 and 2000. The market for calcium bromide in 2003 was approximately 90,000 t with a price of \$400 to 500/t; the market for zinc bromide brines was about 50,000 t. The market exhibits price erosion during periods of low demand, and competition from brine production from effluent hydrobromic acid.

The drilling fluids market is threatened by several factors:

- Consumption of brine fluids on a per-well basis will decline because of the expansion in reuse and recycling of brine fluids.
- Emerging ecological requirements are expected to have an accompanying new demand for “green” drilling fluids.

Biocides

The worldwide bromine-based biocide market is estimated to be about \$1.80 billion with an annual growth rate of 4% to 5%. Approximately half of this is from industrial water treatment applications (cooling towers, paper mills, and so forth.) where the major products are bromine (hypobromous acid); bromochlorodimethylhydantoin (BCDMH); sodium bromide; ammonium bromide; 2,2-dibromo-3-nitropropionamide (DBNPA); 2-mercapto benzothiazole (MBT); and 1,4-bis(bromoacetoxy)-2-butene (BBAB). This market is divided as follows: North America and Canada, 50%; Europe, 25% to 35%; and the rest of the world, 15% to 25%. The other half goes mainly to the swimming pool and spa business as BCDMH and sodium bromide. In this case, the North American fraction is about 75% whereas the rest goes to southern Europe and Australia. The latter market fluctuates according to weather and the mood of the public.

Chemicals

Robert B. Fulton III

INTRODUCTION

This chapter discusses the relationship between industrial minerals and chemical manufacturing. It supplements rather than duplicates the commodity chapters in this volume. Particular emphasis is given to the pertinent chemical elements and to market factors.

Condensing this broad subject into a few pages of this book permits treating only the most important elements derived from industrial minerals. Hydrocarbons, which quantitatively dominate as raw materials for the chemical industry, are omitted, as are the metallic elements and minerals covered in other chapters in this volume, such as phosphorous, potassium, and nitrogen for fertilizers, and titanium dioxide for pigments. The remaining six elements of major importance covered here are boron, bromine, chlorine, fluorine, sodium, and sulfur.

Table 1 affords an overview of the main industrial minerals, the chemical products derived from them, and end uses of the products.

Salt brines have particular importance as raw material sources for the chemical industry. Table 2 is a chart of the chemical compounds derived from four types of brines: (1) Owens Lake-type brines, which are sources of boron and sodium compounds; (2) Midland-type brines, from which bromine, iodine, and chlorides of calcium, magnesium, potassium, and sodium are derived; (3) Searles Lake-type brines, yielding boron, bromine, lithium, magnesium, potassium, and sodium compounds; and (4) Silver Peak-type brines, produced mainly for lithium.

MARKET ATTRIBUTES

Some of the important market traits common to industrial minerals used by the chemical industry are as follows:

1. They are international commodities (e.g., fluorspar, many of which move in foreign trade).
2. Grade and freedom from deleterious elements are important factors affecting their usability in chemical processes. An example is salt (NaCl) used in electrolysis where ultrapure evaporated salt is required to meet rigid specifications.
3. Purified products take on the characteristics of specialty items and command a distinctly higher price than the basic commodity from which they are derived.
4. In practically all cases, chemical users require some sort of purification or beneficiation of the naturally occurring mineral to bring it to specification, and individual specifications may vary from user to user for essentially the same use.
5. In some instances it is necessary to strike a balance between what the vendor can supply and what the buyer requires, with the result that specifications have to be eased to afford the needed materials in marginal cases.
6. Because they tend to be bulk commodities, low cost for handling and transportation is important; so cost may limit the area from which a chemical user can draw its supply.
7. Shipments are usually in bulk and frequently in multiple-car, full-trainload, or full-shipload lots to reduce transport costs, which in turn may require large investment in terminal facilities.
8. Purchases are generally by contracts of 1 year or longer term, with spot buying playing only a minor role.
9. Contract prices are usually fixed in short-term commitments but can vary according to assay, with premiums and penalties for content above or below the norm; general practice, however, is for specifications to be fixed in the contract with minimums set for the desired material and maximums for undesired elements. In longer term contracts, prices are often prorated on labor, fuel, and other vendor processing costs.
10. Suppliers of individual commodities to the chemical industry tend to be few and are generally medium- to large-size producers supplying a few major consumers.
11. The bulk of the mineral volume is for basic chemical uses; sulfur suppliers to sulfuric acid producers and fluorspar for hydrofluoric acid producers are typical examples. These basic chemical products then are used for the manufacture of other products.
12. Shortage of a supply of adequate quality leads consumers to seek substitute sources. For fluorspar, much work is being done on recovery of fluorine from phosphate rock. Success in the form of fluoro-silicic acid or hydrofluoric acid production could, in time, affect the hydrofluoric acid chemical industry.
13. Markets tend to be characterized by cycles of shortage followed by oversupply, with attendant wide price fluctuations.
14. Barriers to international trade can have an adverse effect on the movement of industrial minerals needed by the chemical industry. Antidumping laws, quotas, and tariffs can disrupt or dislocate normal markets.

Table 1. From industrial mineral to inorganic chemical

Commodity	Chemical Formula	Reaction Type	Reagents	Product Formula	Product Name	Uses for End Products
Spodumene	LiAl(SO ₄) ₃	Acid decomposition	Sulfuric acid	Li ₂ SO ₄	Lithium sulfate	Ceramics, glass fluxes, flame colorant, pharmaceuticals, cement additive
		Alkali decomposition	Limestone	LiOH	Lithium hydroxide	Absorption refrigeration, greases, high-strength glass, dyes, wood preservatives
Rock salt	NaCl	Electrolytic	Electricity, water	NaOH	Caustic soda	Miscellaneous chemicals, rayon, pulp and paper, metals, soap, water treatment
				Cl ₂	Chlorine	Miscellaneous chemicals including organics, pulp and paper, water treatment, pharmaceuticals
				H ₂	Hydrogen	Ammonia synthesis, miscellaneous chemicals, metallurgy, hydrochloric acid
		Ammoniation	Ammonia, lime, carbon dioxide	Na ₂ CO ₃	Soda ash	Miscellaneous chemicals, glass, metallurgical, soaps
				CaCl ₂	Calcium chloride	Road treatment, dust suppression
Sylvite	KCl	Electrolytic	Electricity, water	KOH	Potassium hydroxide	General chemicals, fertilizers, detergents, agriculture, batteries, foodstuffs
				Cl ₂	Chlorine	General chemicals, fertilizers, detergents, agriculture, batteries, foodstuffs
				H ₂	Hydrogen	Gas: Petroleum refining, reducing agent, production of high-purity metals
						Liquid: Coolant and propellant, fuel for rocket engines and cryogenic research
Beryl	3BeO•Al ₂ O ₃ •6SiO ₂	High-temperature fluorination	Sodium fluoroferrate	Be(OH) ₂	Beryllium hydroxide	Fluorescent tubes, glass, ceramics, Cu-Al-Ni alloying chemical feedstock
Limestone	CaCO ₃	Calcination	Heat	CaO	Quicklime	Flue-gas desulfurization, fluxes, caustic soda manufacture, effluent treatment, water treatment
				CO ₂	Carbon dioxide	General chemicals, soda ash
Seawater	MgCl ₂	Precipitation	Dolime	MgO	Magnesium oxide	Refractories
Magnesite	MgCO ₃	Calcination	Dolime	MgO	Magnesium oxide	Refractories
Brine	MgCl ₂	Steam decomposition	Dolime	MgO	Magnesium oxide	Refractories, general chemicals, fertilizers, cements
			Not applicable	HCl	Hydrochloric acid	Miscellaneous chemicals, metal pickling, organic chemicals, pharmaceuticals, environmental
Celestite	SrSO ₄	Carbothermic reduction	Coal	SrCO ₃	Strontium carbonate	Glass, ceramics, pyrotechnics
Barytes	BaSO ₄	Carbothermic reduction	Coal	BaCO ₃	Barium carbonate	Glass, ceramics, pyrotechnics, drilling muds, oxygen source, ferrite magnets, medicine, pigments, bricks, metal soaps, superconductors, flux

(Table continued next page)

Table 1. From industrial mineral to inorganic chemical (continued)

Commodity	Chemical Formula	Reaction Type	Reagents	Product Formula	Product Name	Uses for End Products
Basinacsite Monazite Xenotime	Ce, La(PO ₄)	Acid decomposition	Sulfuric acid	Ce,LaO	Rare earth oxides	Glass colorants, polishing powders, lighter flints, arc carbons, catalysts, phosphors, ceramic stains, camera lenses
Zircon	ZrSiO ₄	Chlorination	Chlorine, coke	ZrOCl	Zirconium oxychloride	Metal production, special chemicals
Rutile (natural and synthetic)	TiO ₂	Reductive chlorination	Chlorine, coke	TiCl ₄	Titanium tetrachloride	Pigments, titanium metal, waterproofing agents, glass, ceramics, pharmaceuticals
Chromite	Fe ₃ CrO ₄	Alkali decomposition	Soda ash	Na ₂ CrO ₄	Sodium chromate	Chromium chemicals, oxidants, metallurgy, drilling mud, fanning, pigments, wood preservatives
Pyrolusite	MnO ₂	Acid decomposition Carbothermic reduction	Hydrochloric acid Coal, nitric acid	MnCl ₂ Mn(NO ₃) ₂	Manganous chloride Manganous nitrate	Dry batteries, fertilizers, glass, enamels, catalysts, chemical feedstock, flux
Colemanite	Ca ₂ B ₄ O ₁₁ •5H ₂ O	Alkali decomposition	Soda ash	NaBO ₂	Sodium borate	Detergents, fluxes, bleaches and dyes, pharmaceuticals, glass, water treatment
Bauxite	Al ₂ O ₃ •2H ₂ O	Alkali solution Acid decomposition	Soda ash Sulfuric acid	Al(OH) ₃ Al ₂ (SO ₄) ₃	Aluminum hydroxide Aluminum sulfate	Water treatment chemicals, flocculants, dye mordants, refractories, catalysts
Quartz, silica	SiO ₂	Alkali reaction	Soda ash	Na ₂ SiO ₃	Sodium silicate	Adhesives, cements, deflocculants, soaps, inks, cosmetics
Caliche	NaNO ₃	Reductive chlorination	Chlorine, coke	SiCl ₄	Silicon tetrachloride	Organic chemicals (silicone fluids and rubbers), silicon metal, plasma etching
Phosphate rock	Ca ₅ F(PO ₄) ₃	Acid decomposition	Sulfuric acid	HNO ₃	Nitric acid	Fertilizers, general chemicals, metals and ore processing, urethane, explosives
Brimstone	S ₆	Electric furnace reduction	Silica, coke	H ₃ PO ₄	Phosphoric acid	Fertilizers, detergents, foodstuffs, organic chemicals, water treatment, tanning, refractories
Iron pyrite	FeS ₂	Burning	Air	P	Phosphorus	See phosphoric acid
Fluorspar	CaF ₂	Catalytic oxidation	Air	SO ₂	Sulfur dioxide	Fungicide, insecticide, reducing agent, solvent, chemical feedstock
Seawater, brines	NaBr	Oxidation	Chlorine	H ₂ SO ₄	Sulfuric acid	Fertilizers, chemicals, petroleum refining, pigments, metallurgical
Seawater, brines, caliche	NaI	Oxidation	Chlorine	H ₂ SO ₄	Sulfuric acid	Fertilizers, chemicals, petroleum refining, pigments, metallurgical
				HF	Hydrofluoric acid	Chemicals, fluxes, etchants, metallurgy, isotope separation, semiconductor manufacture, catalyst
				Br ₂	Bromine	Organic synthesis, pharmaceuticals, petroleum additives, water purification, pesticides, batteries
				I ₂	Iodine	Foodstuffs, sanitizers, organic chemicals, dyes, medical, catalysts, metals

* See corresponding chapters in this volume for detailed discussions.

15. Chemical industry consumers may back-integrate for security of supply or for favorable economics by joint ownership, often with experienced mining partners.
16. Conversely, industrial minerals producers may forward-integrate into chemical production.
17. Governmental regulation can affect the usage of chemicals derived from industrial minerals, as is the case of the prescribed phaseout of brominated products under the Montreal Protocol.

ELEMENTS OF MAJOR IMPORTANCE

Boron

Boron is used by the chemical industry mainly as borax (disodium tetraborate decahydrate). It is derived principally from desert evaporite deposits. Major commercial boron minerals are tincal, or native borax ($\text{Na}_2\text{B}_4\text{O}_7 \cdot 10\text{H}_2\text{O}$); colemanite ($\text{Ca}_2\text{B}_6\text{O}_{11} \cdot 5\text{H}_2\text{O}$); tincalconite ($\text{Na}_2\text{B}_4\text{O}_7 \cdot 5\text{H}_2\text{O}$); ulexite ($\text{NaCaB}_5\text{O}_9 \cdot 8\text{H}_2\text{O}$); and kernite ($\text{Na}_2\text{B}_4\text{O}_7 \cdot 4\text{H}_2\text{O}$). Commercially, sodium borates predominate and are supplied by refineries in a variety of grain sizes in either the purified borax form or as fused, crushed, anhydrous borax. Boric acid and boric oxide are also available. The industry defines boron content in terms of B_2O_3 : for example, granular borax decahydrate contains 36.5% B_2O_3 ; 69.1% anhydrous borax; and 56.3% boric acid. These products are sold at 99.5% purity. Raw and semiprocessed ores also are sold. Major world production is in the United States, Turkey, and Russia, each with a million or more tons per year.

Borates are used as fluxes in metal processing, in ceramics, as a constituent of heat-resistant glasses, as an aid in glass fiber manufacture, as cleaning agents, and in textile manufacture. Boron is being used as sodium borohydride in development of hydrogen fuel cells in a public-private project in connection with \$150 million funding by the U.S. Department of Energy (O'Driscoll 2002). Borates are used to suppress forest fires, typically dispensed from aircraft. Borax and boric acid are used as extenders in dye making. In elemental form, boron acts as a neutron absorber in shielding against radioactivity in electricity generation. High level nuclear wastes can be vitrified using boron compounds for shielding radiation (Loft 2002). Organic boron compounds are used as gasoline additives, in insecticides, and in pharmaceuticals. Trifluoroborate is used for manufacture of fluorinated hydrocarbons and in production of antiknock compounds for gasoline. Boron nitride has extreme hardness and stability at high temperature, up to 1,600°F in oxidizing atmosphere. It is used for molten-metal pump parts, transistor and rectifier mounting wafers, and heat-resistant fibers for military composites. Fuels containing boron and hydrogen are outstanding for high energy yield but have not been widely used because of pollution effects and high cost. Table 3 describes boron starting materials and end products.

According to the U.S. Geological Survey (USGS; Lyday 2002a), U.S. production of boron minerals and compounds in 2001 was 1.05 Mt gross weight compared to 1981 at 1.342 Mt, and 1991 at 1.24 Mt, illustrating a continuing decline. Approximate year-end free on board (f.o.b.) prices, quoted per ton in bulk for 1990 and 2001, are as follows:

	1990, \$	2001, \$
Boric acid (99.9%, technical grade)	775–784	788
Pentahydrate borax (technical grade)	321	376

Opportunities for wider applications of boron compounds, in addition to the growth in established fields of use, include in glass fibers for reinforced plastics for weight reduction in automobiles, in fuels, and as a possible replacement of fluorspar as a fluxing agent in steelmaking. Boron's capability of forming a large number of

coordination compounds offers a venue for investigation through which a variety of diverse products would result.

Bromine

Bromine compounds are used in flame retardants (40%), drilling fluids (24%), pesticides (12%), water treatment chemicals (7%), and others (17%) (Lyday 2002b). A variety of organobromides are used in agriculture as fumigants for controlling nematodes in soil and insects in grain and seed storage. Elemental bromine is consumed in disinfectants and bleaching agents. Sodium, potassium, and ammonium bromides have minor uses in textile fiber manufacturing, photography, and medicines. Bromine compounds are used in small amounts in making dyes, resins, leather, and rubber products as well as in producing textile intermediates and finishing agents. Expanding uses are in flame retardants and extinguishing agents and for gas- and oil-well completion fluids as calcium, sodium, and zinc bromides. Biocides containing bromine used in industrial cooling are replacing those based on chlorine for environmental considerations.

According to the USGS (Lyday 2002b), U.S. refinery production of bromine in 2001 was about 212,000 t compared to 230,000 t in 1998. Current U.S. production compares to production capacity of about 260,000 t p.y. Israel was the second largest producer in 2001 at 206,000 t. Total production worldwide in 2001 was about 543,000 t.

Average value of bromine sold or used in 2002 was 75 cents/kg, compared to about 88 cents/kg at year-end 1990; it had increased from 45 cents in the mid-1960s to about 60 cents in the early 1980s. The price is expected to increase mainly because of the increased cost of process energy. The reader is referred to the chapter on bromine in this volume for further information.

Chlorine

A number of principal chlorine consumers in the chemical industry are situated in the producing regions and in many cases are back-integrated with obvious advantages. Consumers who are not back-integrated purchase either chlorine or chlorine compounds such as hydrochloric acid, chloroform, ethyl chloride, ethylene dichloride, carbon tetrachloride, perchlorethylene, and the like, depending on process requirements and economics. Choice of purchase mix is determined by relative costs, for example, buying either carbon tetrachloride or chlorine and hydrocarbons for in-house production of the chlorocarbon. This choice has ramifications, such as the internal generation of HCl produced as a by-product of hydrocarbon chlorination and of fluorination. The internally produced HCl can then be oxidized back to chlorine in a closed circuit, thereby reducing the intake of purchased chlorine and reducing costs.

Similarly, manufacturers of polyvinyl chloride (PVC) can choose to buy ethylene dichloride or, if they have chlorine and ethylene available, they can elect to make it themselves. Recycling by-product HCl from vinyl chloride monomer plants is widely practiced with use of HCl in oxychlorination to make ethylene dichloride.

Principal chemical industry uses for chlorine are for intermediates and for synthesis of organic and inorganic chlorides used in plastic solvents, agricultural chemicals, automotive fluids, sanitation products, and so forth. Another use of ethylene dichloride is for making solvents, such as trichloro- and perchloroethylene. Ethylene dichloride also is a less expensive, though less effective, lead scavenger than ethylene dibromide used in fuels as antiknock compounds; lead, however, has been eliminated almost entirely from gasoline intended for spark-ignition engines, although small amounts of lead still are used in automotive fuels and in aviation gasoline.

An important inorganic intermediate used in the manufacture of titanium dioxide (TiO_2) pigment is titanium tetrachloride, which is manufactured by the so-called chloride process that now supplants the older sulfate process.

Chlorine also is required for the manufacture of organic intermediates such as adiponitrile from butadiene. Adiponitrile is a feedstock chemical used in the production of Nylon 6,6. In this case, both chlorine and caustic are consumed, fortunately, in the same ratio as produced by electrolysis of brine. This ratio, known industrially as one electrochemical unit (ECU), consists of 1.0 t of chlorine to 1.1 t of caustic soda and requires 1.75 t of salt to produce one ECU.

Growth of elastomeric products, made using chlorine, butadiene, and caustic or using hydrochloric acid and acetylene, has contributed significantly to world demand for chlorine.

Product obsolescence can play an important role in the chlorine market, as in the case of by-product chlorine from metallic sodium manufacture. The amount of chlorine available from sodium production decreased as demand for leaded gasoline declined; lead was amalgamated with sodium as a step in the manufacture of lead antiknock compounds.

Phosgene is another chlorine chemical important to chemical processing, for example, in the production of agricultural chemicals, isocyanates, and other fiber intermediates and elastomers.

Overall domestic growth is generally flat or slightly declining because of (1) nonchlorine-based processes supplementing some of the chlorine requirements; (2) slackened growth in cyclic organic detergents and chlorinated solvents, which have been criticized on environmental grounds; (3) leveling off in growth of other major products containing chlorine, such as vinyl chloride; (4) the problem with dioxin poisoning and its negative influence on the bleaching of pulp and paper; and (5) curtailment of chlorofluorocarbon manufacture and use. An exception is PVC, where growth is currently positive because of increased building construction in a growing economy and relatively low interest rates.

Environmental issues profoundly affect the chlorine business. Discontinuing use of lead additives and curtailing carbon tetrachloride production are prime examples. The generally accepted thesis that chlorine in the upper atmosphere is responsible for a chain reaction destroying the Earth's protective ozone layer eventually may lead to reductions in manufacture and use of chlorine compounds.

Chlorine-caustic market pricing provides insight into the pricing mechanism at work. Chlorine pricing is characterized by vendor willingness to make long-term contracts at a set price. Such contracts, with terms of 5 to 7 years, provide the seller with an adequate, though modest, return on investment. ECU prices are generally equally divided between chlorine and caustic. The chlor-alkali manufacturers can find advantage by raising caustic prices, thus compensating for any weakness in chlorine and giving a slight increase in overall profitability. Industry return on investment is not so great as to give strong incentive to accelerate expansion.

Since most of the chlorine produced in the United States is for captive use (about 60%), the manufacturers have used merchant sales to achieve high rates of operation, thereby minimizing unit costs of their captive requirements. These merchant sales are largely influenced by proximity of vendor to purchaser. The overall market demand must be viewed in terms of chlorine chemicals; some of the ostensibly captive chlorine requirement of manufacturers is truly just one move downstream along the route to a final product. For chlorinated hydrocarbons, the chlorine manufacturer takes the next step of treating hydrocarbons and selling the chlorinated compound.

An interesting change of technology in chlorine manufacture is the decline of mercury cells in favor of diaphragm cells because of environmental measures to control mercury, even though diaphragm cells cost more to operate but require less initial investment. Before this restructuring, the trend was toward increasingly larger mercury cells that produced 20 t of chlorine per day. The emphasis has changed so that the majority of chlorine produced by brine-electrolysis comes from diaphragm cells. The development of the dimensionally stable electrode eliminates the problem of gradual chlorination of the organic binders used in graphite anodes that resulted in inefficient cell operation as the anodes disintegrated. An electrode made of titanium metal, protected by a film of inert metal oxide, permits construction of larger cells with higher current densities and results in a 3- to 5-year electrode life compared to 3 to 6 months for graphite electrodes. Diaphragm cells with a production capacity of 3 tpd of chlorine have a life of 9 months to 1 year and are limited only by problems with the diaphragm itself. Solving difficulties with the diaphragm is centered on new materials and construction techniques.

A further cell modification is a bipolar cell in which anodes are connected directly to adjacent cathodes to reduce voltage drops now experienced in busbar connections between cells. Development of bipolar membrane cells will permit higher concentrations of caustic in the cell, thereby eliminating subsequent costly evaporation.

In 2002, percentages of chlorine produced in the three types of electrolytic cells were diaphragm (78%), mercury (14%), and membrane (6%); the balance of chlorine and caustic production (2%) is by-product from magnesium and sodium metal production (Kostic 2002b).

The long-range market outlook is continued modest, steady growth in chlorine use by the chemical industry despite the adverse factors cited.

Fluorine

Fluorine in the chemical industry is used mainly as a constituent of fluorocarbons and in organic fluorides. Hydrofluoric acid is the intermediate for practically all fluorine chemicals. It is produced by reacting fluor spar with sulfuric acid to yield hydrogen fluoride gas and calcium sulfate. The gas usually is liquefied as anhydrous hydrogen fluoride, but it may be adsorbed in water to make aqueous hydrofluoric acid, usually 70% HF. In commercial practice, about 2.2 t of acid-grade fluor spar (97% CaF_2) are required to make 1 t of hydrofluoric acid. Contaminants found in commercial, acid-grade fluor spar are calcium carbonate, silica, and sulfur; maxima are usually set by the consumer. Other objectionable constituents, for which maxima may be set, include arsenic, chloride, and phosphate. Grain size and moisture content are also specified.

The fluorocarbons are a large family of useful compounds. The first to obtain commercial acceptance were refrigerants; they still constitute a major part of the market. They are used in the manufacture of plastics that are characterized by chemical inertness, toughness, and electrical resistivity. Other fluorocarbons are used as fire-extinguishing agents, dielectrics, surfactants, anesthetics, and pharmaceuticals.

Concern for the ozone-depleting potential of chlorofluorocarbons has led to the development of alternatives that contain less or no chlorine in the molecule and do not deplete ozone in the stratosphere. Because of environmental concerns, the United States ended chlorofluorocarbon use in aerosol propellants. In other applications, substitutes (i.e., "not in kind" substitutes) are sought. Most alternative fluorocarbon molecules contain a higher percentage of

fluorine atoms than the chlorofluorocarbons they replace. Depending on the amount of the market captured by not-in-kind substitutes and the amount gained by the new, higher fluorine-containing alternatives, fluorspar usage by the chemical industry may stay about level or even increase moderately.

Inorganic fluorides are produced by reacting hydrofluoric acid with the appropriate base or basic salt. Principal uses of inorganic fluorides are outside the chemical industry, such as (1) the use of synthetic cryolite (Na_3AlF_6) in the production of aluminum metal; (2) the relatively minor uses of sodium and potassium silicofluorides for fluxes and as constituents of enamels and glass; (3) the use of aluminum fluoride as brazing flux; (4) the use of sodium-aluminum-fluoride in resin-bonded grinding wheels; and (5) the use of sodium silicofluoride in water supply systems to control human tooth decay.

Hydrofluoric acid is a source of fluorine in reactions with uranium to produce gaseous uranium hexafluoride from which U^{235} is diffusion separated from the more abundant U^{238} . Hydrofluoric acid is also widely used as a catalyst in the alkylation of petroleum during high-octane gasoline production. A minor use of hydrofluoric acid is for etching glass, such as electric light bulbs.

The reader is referred to the chapter on fluorspar in this volume for further information.

Sodium

Caustic soda, soda ash (sodium carbonate), and salt cake (sodium sulfate) are useful to the chemical industry mainly as sources of alkalinity and the sodium ion. Supply of caustic is entirely dependent on chlorine production (see section on Chlorine in this chapter).

Demand for caustic is related, in part, to chlorine, but caustic is unrelated to chlorine in many of its applications. For example, the organic intermediate adiponitrile, mentioned previously, is produced from butadiene. Where chlorine and caustic are related in direct proportion (see section on Chlorine in this chapter) to the ECU, a price advantage for the total ECU is possible because the vendor has no surplus of either commodity. Generally, however, the pricing of the two is independent.

Various sodium raw materials may be used for the manufacture of certain sodium compounds such as bicarbonate, cyanide, perborate, nitrate, and silicate. In making sodium bicarbonate and sodium silicate, soda ash is the usual starting material, but caustic is sometimes used for silicate.

Caustic is used in making such diverse products as cellophane, nylon intermediates, and pigments. It has important applications in waste treatment processes and in pulp, paper, and alumina manufacture. Increased demand for these applications led periodically to tight supply and rising prices, partly because chlorine demand failed to keep pace with demand for caustic. On occasion, environmental concerns adversely impacted chlorine use in its principal markets, including pulp and paper, chlorofluorocarbons, chlorinated solvents, and PVC, whereas caustic soda demand continued its steady, though moderate, growth. As a result, the price of chlorine dropped and caustic rose. The discrepancy between weak caustic supply, dependent on chlorine production, and steadily growing demand can create a gap, causing instability in the market on an ECU basis.

Shortages or noncompetitive prices for caustic push users to buy soda ash for alkalinity requirements. An example is trona (sodium sesquicarbonate), which can be used by itself or converted to caustic. Six companies in the United States produce soda ash, which is used principally in the manufacture of glass (49%); in chemicals, including caustic (26%); in soaps and detergents (11%);

in pulp and paper (2%); in flue-gas desulfurization (2%); and in miscellaneous uses. In 2002 U.S. production was 10.5 Mt, compared to world production estimated at 37.1 Mt. (Kostic 2002a).

Sulfur

Sulfur's usefulness is so widespread and pervasive in the chemical industry that its consumption closely follows the pattern of industrial activity. Tables 4 and 5 provide a clear condensation of the role of sulfur and sulfuric acid derivatives in organic and inorganic reactions and process applications.

Frasch process sulfur was formerly a strong factor in meeting sulfur supply requirements, but the last Frasch mine in the United States closed in 2000. No new, important supplies of sulfur are coproduct sulfur from natural gas and petroleum and, increasingly, sulfur obtained as the by-product of pollution control.

Marketing of sulfur reflects the well-established preference of bulk consumers for deliveries in liquid form. High labor and energy costs for remelting, together with environmental aspects, continue to stimulate the preference for transport and use of liquid sulfur.

U.S. sulfur production in 2002 was about 9.27 Mt, of which recovered elemental sulfur was 8.5 Mt and other (mainly as by-product sulfuric acid) was 770,000 t. Imports were 2.9 Mt. Comparative figures for 1998 were 11.7 Mt of production consisting of 1.8 Mt Frasch, 8.3 Mt of recovered, and 1.61 Mt of other, with imports the same at 2.9 Mt. Average prices in 2002, free on board (f.o.b.) producing plant, were \$11.84/t, compared to \$29.14/t in 1998, when high-cost Frasch was a factor in the pricing.

The outlook is for increased sulfur supply coming from pollution control. For additional information, the reader is referred to the chapter on sulfur in this volume.

ENVIRONMENT

As an example of industrial sensitivity to environmental concerns, U.S. Borax, Inc., a major producer, is acting to ensure that its activities promote sustainable development, including low environmental impact at its operations and enhancement of standards of living by its products and their contribution to economic development. In line with these objectives, the Industrial Minerals Association—North America (IMA—NA) was formed in 2002, and U.S. Borax is a member of its soda ash and borates section. The aim of IMA—NA's 38 member organizations is to coordinate industrial minerals producers' actions in governmental affairs, safety and health, environmental concerns, operations, and engineering (Industrial Minerals Association—North America 2003).

Sustainable development has become the catchword of the chemical industry. Goals in the pursuit of sustainable development are economic, environmental, and social to maximize effective use of resources, to minimize environmental impacts of operations, and to protect the health and safety of employees and of the public.

The toxicology branch of the U.S. Centers for Disease Control and Prevention has about 50 studies in progress to assess safe and unsafe levels of certain chemicals and has released a survey of 116 chemicals measured in blood and urine samples collected nationwide. Findings to date have focused on exposure to lead, organophosphate pesticides, dioxin and related chemicals, and other selected chemical compounds (Hileman 2003).

The United States approved the Montreal Protocol limiting the production, trade, and use of chemicals associated with destruction of ozone in the stratosphere; this affected mainly chlorofluorocarbons. An amendment in 1997 added methyl bromide to the list of controlled substances and requires licensing for the export and import of all substances controlled under the Protocol. Another

amendment in 1999 added bromochloromethane to the list for phaseout of production, consumption, and trade (*Chemical Marketing Reporter* 2002).

OUTLOOK

The role of these industrial minerals in the chemical industry ensures their vitality in U.S. and world economies. As noted, each fills significant human needs and will continue to be drawn upon to fulfill their roles in chemical production.

ACKNOWLEDGMENTS

The contributions of Lynn S. Jacoby of DuPont in preparation of the sections on chlorine and sodium are gratefully acknowledged, as are the commodity specialists of USGS, whose work has been indispensable in the preparation of this chapter. The peer review and inputs by David E. Morse and his associates in the Minerals Information Team at the National Headquarters of the USGS in Reston, Virginia, are gratefully acknowledged.

Chromite

John F. Papp and Bruce R. Lipin

INTRODUCTION

Chromite ore is mined mostly for metal content; it has useful properties, however, for the refractory and foundry industries. Louis Nicolas Vauquelin first isolated chromium from the mineral crocoite in 1797. He called the new element chromium because its compounds had a wide variety of colors. *Χρῶμα* is Greek for color, which is *chroma* in Latin. One of these compounds was a yellow pigment that became popular; as a result, paint was the first commercial application of chromium. Soon thereafter chromium was discovered in chromite (FeCr_2O_4), a much more common mineral, from the Ural Mountains.

On the periodic table, the element Cr has many name variations: *chromium* is the American name of the element, *chrome* is the British and French name, *chrom* is the German name, and *xpom* (in the Cyrillic alphabet) or *krom* (in the Latin alphabet) is the Russian name.

CHROMIUM IN THE 20TH CENTURY

The United States started the 20th century both producing and consuming chromite, but today it is solely a chromium consumer. In 1900, “chromic iron ore” described what is now called chromite ore. At that time, it was used as an alloying element, in chemical compounds, and in refractory materials. The United States produced 142 t of chromite in 1900, 0.27% of world production. U.S. production had averaged 2,200 tpy from 1880 through 1896, and there was no production from 1897 to 1899. Production increased during World War I and World War II, and ended in the mid-1960s.

Chromite consumption peaked in 1943 as a result of World War II mobilization, but did not reach maximum consumption until 1977. The United States was the major world chromite consumer until after the war. Chromite consumption in the chemical industry grew in the years from 1900 to 2002. Metallurgical industry consumption peaked during 1956 and 1957. Chromite-containing refractory production grew until the mid-1960s and then declined because of technological developments and environmental concerns.

Isaac Tyson Jr. (1792–1861) was responsible for starting U.S. chromite production and chromium chemical manufacturing. He studied geology, mineralogy, and chemistry in France, and subsequently developed the first chromite ore mines in the United States. He also established the first U.S. chromium chemicals plant, the Baltimore Chrome Works, in Baltimore, Maryland, in 1845. The plant closed in 1985. Some of Tyson’s mines are preserved today in the Soldiers Delight Natural Environmental Area northwest of Bal-

timore. Tyson was inducted into the National Mining Hall of Fame and Museum in 1996.

The United States no longer accounts for significant chromite production, but continues to be a major consumer of chromium. Ferrochromium was once produced in the United States from imported chromite, but now nearly all ferrochromium is imported. Ferrochromium is consumed predominantly by the stainless steel industry, a sector that has continued to show significant growth.

Chromium is important in metallurgy as an alloying element. Chromium and tungsten were alloyed with iron to make tool steel. Chromium also was used to harden armor plating. These uses, and chromite use as a refractory in steel-producing furnaces, made material containing chromium strategically critical material World War I. Stainless steel was first produced in France, Germany, the United Kingdom, and the United States between 1910 and 1920 when chromium was alloyed with iron. Once the role of chromium, nickel, and other alloying elements was understood, stainless steel became an integral part of the steel industry. In 2002 stainless steel accounted for more than 2.4% of U.S. steel production, averaging 2.2% between 1998 and 2002. Stainless steel production has been growing and that growth is expected to continue. Stainless steel accounted for 75% of U.S. chromium consumption in 2002. Superalloys are engineering alloys of chromium and nickel for demanding applications in aggressive environments that were unknown in 1900. They are used in the internal workings of jet engines, an important strategic use of chromium, and in stationary turbine electrical power generation, another important critical use.

The term *chromite* is used in many different ways. Terminology is not consistent throughout the industry or among academic disciplines that study chromium. For this chapter, the *mineral chromite* describes the mineral itself. *Chromite ore* refers to rock in the ground that is economically minable for the mineral chromium content and run-of-mine ore (i.e., material removed economically from the ground). *Chromite* refers to products made from chromite ore and supplied to the marketplace. For trade purposes in the Harmonized Tariff System, chromite is called *chromite ore and concentrate*, which is made from chromite ore. This description frequently is shortened to chromite ore, chromium ore, chromite, chrome ore, or chrome. The terms are used synonymously and may appear confusing to the general readership. Historically mines supplied minimally processed material, so there was little difference between chromite ore and chromite products. Today most chromite ore is processed before it reaches the marketplace.

GEOLOGY

Mineralogy

Chromium is found in a wide variety of oxide and silicate minerals in the earth's crust. At standard temperature and pressure, chromium is a metal; it does not, however, occur in the native state. The most important chromium-bearing mineral is chromite, which is the only ore of chromium. It is in the spinel group with the general chemical formula XY_2O_4 , where X and Y represent divalent and trivalent metal ions, respectively. Figure 1 shows spinel minerals in a prism diagram with end member compositions at each corner. Because most spinel end members form at high temperatures, compositions of the mineral chromite form complete or extensive solid solutions within the prism.

The base of the prism consists of aluminum- and chromium-bearing spinels with no trivalent iron (or titanium). Compositions become richer in trivalent iron and poorer in divalent iron the higher they occur in the prism. Care is necessary using this nomenclature because the series based on aluminum and the MgAl_2O_4 end member is named *spinel*.

Compositions of the mineral chromite occupy the volume shown in Figure 1. Lode chromite ore deposits are of two types: stratiform and podiform. Compositions differ in the two types of

deposits. In podiform deposits the trend marked "A" is a ramp leading from high Al values to high Cr values with very low Fe^{3+} (or Ti^{3+}). This ramp leads to a cylinder in which compositions of stratiform and podiform deposits overlap, but podiform deposits generally have lower Fe^{3+} (or Ti^{3+}) than do stratiform deposits. Other minor constituents include nickel, zinc, and manganese (Table 1).

Ions in spinel-group minerals form a close-packed, cubic, face-centered lattice that imparts a relatively high density; the typical specific gravity of commercial chromite product is 4.5 to 4.8 g/cm³. The mineral chromite is black with a metallic to dull luster and yields a dark brown streak, distinguishing it from other black spinel-group minerals, which typically have a white streak (e.g., magnetite). The mineral chromite is opaque to slightly translucent in thin section, depending on the amount of trivalent iron present; it is opaque if it contains very little Fe^{3+} but slightly translucent if it contains more than a few percent Fe^{3+} . The mineral chromite with very low amounts of Fe^{3+} (less than a few percent) is nonmagnetic; higher amounts of Fe^{3+} make it weakly magnetic. Hardness is typically 5.5 to 6.5 on the Mohs scale. The mineral chromite typically does not show cleavage and exhibits conchoidal to uneven fracture.

Origin

Four types of chromite ore deposits occur as either lode deposits or secondary deposits. Lode chromite ore deposits comprise stratiform and podiform deposits, whereas secondary chromite ore deposits comprise laterite and placer deposits.

Stratiform deposits are found in layered igneous complexes and podiform deposits occur as irregularly shaped pods or folded lenses in lower portions of ophiolites. Economic stratiform chromite ore deposits have been found only in those layered igneous complexes older than 2.06 Ga. Ophiolites are pieces of mantle and oceanic crust that have been thrust over continental crust or island arcs by tectonic motion over time. For many years ophiolites were thought to be geologically young (<1 Ga), but Kusky, Li, and Tucker (2001) demonstrated that an ophiolite in China with chromite ore deposits is as old as 2.505 Ga. In addition, Stoen (1987) interpreted the approximately 3.5-Ga-old chromite ore deposits at Selukwe, Zimbabwe, to be of ophiolitic origin.

Secondary chromite-containing deposits exist as laterite deposits derived from weathering and leaching of peridotite host rock that contains 1% to 2% of the mineral chromite; they are not commonly ore grade. Large peridotite bodies in tropical climates with favorable topographic environments (not too mountainous) can undergo chemical weathering that results in residual soils. Subsequent leaching of silicate minerals helps accumulate chromite mineral. These lateritic soils make it easy and inexpensive to concentrate chromite mineral from its matrix. Such deposits are mined in Indonesia and Vietnam. Although production from these deposits is a tiny fraction of world production, their potential is enormous.

Placer chromite results from erosion of peridotite host rock. The relatively dense chromite mineral is concentrated as lag deposits on beaches or in streams. These have the least economic importance of the four types of chromite mineral deposits. None are currently being mined.

Some controversy exists about the origin of lode chromite ore deposits. In many layered igneous complexes it appears that repetitive layers were produced by multiple injections of magma into the rock chambers. A new magma injection commonly marks the beginning of a new cycle, with chromite mineral crystallizing typically with olivine or pyroxene in the ratio of approximately 98:1 silicate to chromite mineral. Then only chromite mineral crystallizes to form a layer of massive chromitite, or a mixture of silicate and chromite mineral in widely varying proportions. Temporary

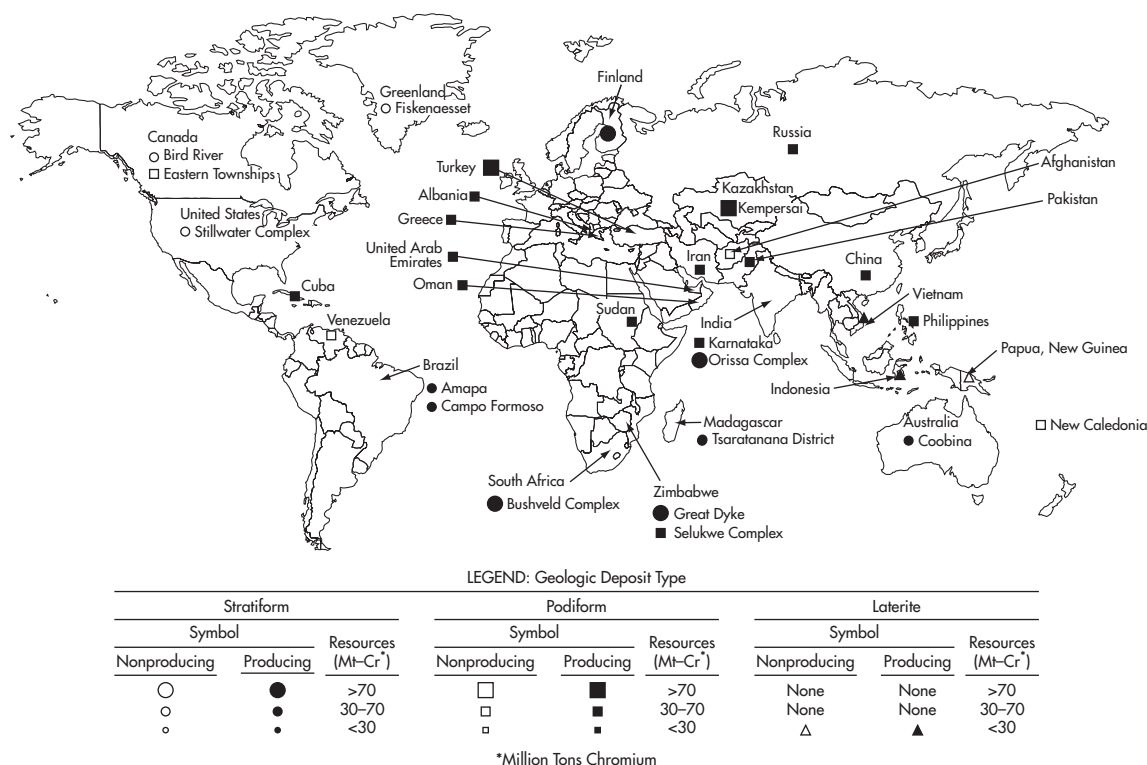

Figure 2. Location, geologic type, and size of major chromite ore deposits

cessation of silicate precipitation is not the normal sequence in fractional crystallization, suggesting that something disrupts the system. Two hypotheses have received special attention in explaining this phenomenon. Hess (1960) promoted the idea that new magma comes in contact with preexisting magma in the chamber (magma mixing). Irvine (1977) suggested that newly injected magma could mix with a granitic component, and later data from the Bushveld Igneous Complex (Schoenberg et al. 2001) supported the idea. The other hypothesis was first suggested by deVilliers (1970) and Cameron (1975), and later explored by Lipin (1993). Their idea was that temporary pressure increases within the magma chamber cause only chromite mineral to crystallize, an effect that Sen and Presnall (1984) verified experimentally.

Several ideas regarding the origin of podiform chromite ore deposits in ophiolites are based on the complicated structural setting and varied shapes of the deposits. These fall into the following categories: (1) residue from partial melting in the mantle; (2) crystallization from a mafic magma during deformation; (3) magma conduits in which pyroxene was dissolved out of peridotite through which it flowed, thus changing the magma composition, and where only chromite mineral crystallized; and (4) interaction of metamorphic fluids in the mantle with peridotite to form chromite mineral.

Abundance

Chromium is the 13th most common element in the earth's crust at about 185 ppm; it is the 26th most common element in seawater at about 0.2 ppb (Taylor and McLennan 1985). The highest concentration is in igneous rock at 0.06% (Parker 1967).

Chromite mineral commonly occurs in mafic and ultramafic rocks, which cover large portions of the Earth's surface. Peridotite, an ultramafic rock predominated by olivine, is the common host for economic chromite mineral deposits. Chromite mineral deposits

also occur in pyroxenite and rarely in anorthosite. Peridotite contains 1% to 2% chromite mineral as an accessory mineral. Most economic chromite mineral deposits contain concentrations of at least 25% chromite mineral. Exceptions are laterites in Indonesia and Vietnam derived from weathering of peridotite.

Mafic rocks, mainly basalt, also contain the mineral chromite; flood basalts, however, which represent the most voluminous of these rocks and cover thousands of square kilometers, rarely contain mineral chromite. For example, the average chromium content of Columbia River Basalt is less than 100 ppm; thus, chromium is dispersed in very low concentrations in common mafic minerals. Oceanic basalts have more chromium on average and mineral chromite occurs in trace amounts. For example, Hawaiian basalts contain about 400 ppm chromium, which is high enough to form the mineral chromite; its grain size, however, averages only 29 µm. The small grain size makes bulk separation difficult.

Although many rocks contain chromium or mineral chromite, they are not potential hosts for economic mineral chromite deposits. Lipin (1983) showed that only mineral chromite occurs with enough chromium to be an ore.

Distribution of Major Deposits

Figure 2 shows the distribution of major chromite ore deposits around the world. Ophiolite complexes are more abundant than stratiform igneous complexes older than 2.06 Ga. About 70% of all chromite ore mined in 2002 came from stratiform deposits (Papp 2005). About 95% of the world's chromite ore resources are in the Bushveld Igneous Complex of South Africa and the Great Dyke of Zimbabwe; the majority is in the Bushveld. The largest concentration of podiform chromite ore is in the Kempersai area of Kazakhstan (Papp 2001). Since the dislocation of traditional markets that resulted from the dissolution of the Soviet Union in 1991, chromite

ore production in the Bushveld from 2000 through 2004 has been two to three times greater than that of the Kempersai.

The Bushveld Complex is one of the largest layered intrusions in the world, occupying about 64,340 km². The great amount of magma intruded into the rocks of the Bushveld Complex cooled very slowly. As a result, different minerals crystallized from the liquid magma at different times, forming layers with different mineralogies. The cyclic layering indicates that the process of intrusion and cooling occurred often over a long period of time. Geologists call the differentiated mineral layers the *upper*, *middle*, and *lower groups*. (Each of these groups is further subdivided into layers; e.g., UG2 means layer 2 in the upper group and LG6 means layer 6 in the lower group.) All economic chromite layers originated at or about 2.06 Ga. The Bushveld contains more than 11 billion t of total resource (Vermaak 1986). One layer, informally called the Steelport Seam, contains 1.5 billion t of resource. The Steelport Seam can be traced over much of the Bushveld.

The Bushveld Complex also is the world's largest repository of platinum and palladium, some of which are found in chromite seams.

The Kempersai (also known as the Kimpersai or Kimpersaisky) area of the Southern Urals in Kazakhstan is home to the world's largest podiform chromite ore deposits, covering about 1,200 km². These deposits occur where parts of the ocean floor were obducted over continental rocks. This area has more than 75 times the reserves and about 4 times more production than the podiform deposits of Turkey, which rank second in podiform chromite production and reserves.

TECHNOLOGY

Exploration Techniques

The Bushveld Complex (South Africa), Great Dyke (Zimbabwe), and Kempersai (Kazakhstan) have been thoroughly investigated through geological mapping, geophysical methods, and exploration drilling, so these chromite ore deposits are well known. Resources in the Bushveld Complex can easily be upgraded from inferred to demonstrated, or from indicated to measured, by additional exploration. Because podiform chromite ore bodies are irregular in shape and unpredictable, gravity and electrical methods may offer some promise as exploration tools.

Laterites that develop over ophiolite deposits may indicate the presence of chromite ore. Such laterites are extensive in area and the chromite ore they contain is relatively easy to remove and concentrate.

Reserves and Resources

Resources presented here are based on public information. Sources include individual company reports, the International Chromium Development Association (ICDA) Web site (www.chromium-asoc.org), government documents, and domestic government reports such as DeYoung, Lee, and Lipin (1984); Thomas and Boyle (1984); and Boyle, Shields, and Wagner (1993).

The revised resource estimates based on company reports may be more accurate because they are more recent and are based on detailed geologic, mining, and economic information from company engineers and geologists responsible for mine planning; resource estimates may be based on different criteria, however, depending on the company and country. Unfortunately, for many locations resource information has not been recently published. Estimates were made when there were no reported data.

Reserves for Kazakhstan were based on resource categories used in the former Soviet Union (now the Commonwealth of Independent States [CIS]). That system emphasized certainty of physi-

Figure 3. World chromite ore reserves by country. The bar chart shows countries with smaller reserves at a smaller scale so that their relative size is apparent.

cal resources and downplayed the economics of recovery. Kazakhstan reserves are likely to be discounted when recovery economics are factored in. South African reserves are based on the reports of major chromite producers in accordance with reporting standards for such business information. As a result, South African reserves are constrained by reporting standards and by the geographic area of mineral title. The reserves of Zimbabwe are based on resource analyses by Boyle, Shields, and Wagner (1993). These reserves are likely to be discounted when property boundaries and economic factors are taken into account. In addition, tax codes and the high cost of drilling may affect how a company chooses to prove reserves and how much to delineate.

The United States has no chromite ore reserves; it does, however, have resources that could be developed for mining. The U.S. reserve base is estimated to contain about 2 Mt of chromium. The largest U.S. chromite mineral deposit is the Stillwater Complex of Montana.

World reserves of chromium are about 213 Mt, and the world reserve base of chromium is about 444 Mt. The world wide distribution of 1.52 billion t of chromium in identified chromite ore resources is Africa, 52%; Asia, 38%; Europe, 5%; the Americas, 3%; the Middle East, 2%; and Oceania, 0.1%. The U.S. Geological Survey (USGS) reports reserves and reserve base information annually in *Mineral Commodity Summaries*. Figure 3 shows world chromite ore reserves.

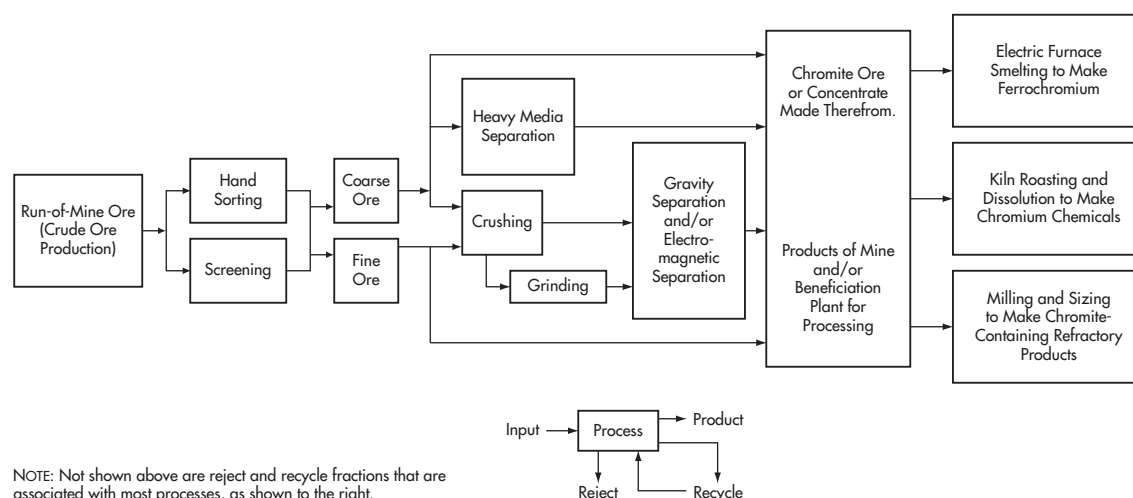

Mining, Beneficiation, and Processing

Recovery of chromite from chromite ore includes surface and underground mining methods. Beneficiation produces chromite, the marketable product containing chromite mineral, and ranges from hand sorting to gravimetric and electromagnetic separation methods. Processing of chromite ore to produce chromite for refractory, chemical, and metallurgical markets involves crushing and grinding, and size sorting by pneumatic and hydraulic methods. Chromite processing by the chemical and metallurgical industries includes kiln roasting and electric furnace smelting (Table 2 and Figure 4). The flow chart of Figure 4 shows beneficiation and processing, which may be carried out at the mine site, at a plant serving several satellite mines in one geographic area, or at a plant associated with an end user. Today, chromite ore is beneficiated to produce physically and chemically uniform products before reaching the marketplace.

The nature of the deposit dictates the mining method(s). The characteristics of a chromite ore deposit that must be considered are whether it is stratiform or podiform, high grade or low grade,

Table 2. Factors used to characterize chromite deposits and mining, beneficiation, and processing methods applied to those deposits

Mineral	Mineral Appearance in Ore	Deposit Types	Host Rock	Mining Method	Beneficiation Method	Processing Method
Chromite (a spinel structure oxide mineral)	Massive (spinel mineral of varying chemistry) Disseminated (spinel mineral intermixed with other minerals)	Stratiform (bedded) Podiform (lenticular)	Mafic Ultramafic	Surface Subsurface	Hand sorting Screening Gravity concentration Electromagnetic separation Heavy-media separation	Sizing Roasting and dissolution Smelting

**Figure 4. Chromite ore mining, beneficiation, and processing**

subsurface or near surface, or massive or disseminated. Because surface mining typically is less expensive than underground mining, it is preferred.

Beneficiation depends on the characteristics of the ore deposit and on the mining methods used. For example, an operation extracting only high-grade ore may require only hand sorting and screening. Beneficiation is necessary when chromite mineral is mixed with other minerals because of geologic conditions or when mechanized mining methods are nonselective.

Beneficiation methods depend on the end use and may include increasing chromic oxide content, the chromium-to-iron ratio, or alumina content. Reducing silica content or eliminating waste rock associated with chromite ore also may be desirable. Certain sizes may be selected for or rejected as well. Techniques used to accomplish these tasks further depend on the physical properties of the minerals present. Beneficiation cannot change the chemical characteristics of the chromite mineral; because chromite ore is a mixture of minerals, however, altering the mineral mixture can change its characteristics for its respective market. A deposit producing lumpy ore in which chromite mineral is easily distinguished visually may require only hand sorting and screening; otherwise, heavy media separation can be used. A deposit that yields chromite ore thoroughly mixed with gangue minerals may require milling and sizing followed by gravimetric or electromagnetic separation to produce marketable chromite products. Beneficiation methods are used to process tailings when sufficient quantities have been stockpiled (see the By-products and Coproducts section of this chapter).

Specifications

Chemical and physical specifications for chromite vary among producers and consumers. Chromite producers make chemical specifica-

tions of their products available. Table 3 shows chemical specifications of several chromite products by end use and by source.

In the United States, the American Society for Testing and Materials (ASTM) sets chemical and physical specifications for chromium materials. Other organizations also promulgate specifications for chromium materials. The Defense Logistics Agency (DLA), in cooperation with the U.S. Department of Commerce, maintains purchase specifications for chromium materials contained in the National Defense Stockpile (NDS). The U.S. Department of the Treasury, in cooperation with the U.S. Department of Commerce and signatories to the General Agreement on Tariffs and Trade, maintains definitions of chromium materials for recording trade and applying tariffs.

The import category "chromite ore and concentrates made therefrom" of the Harmonized Tariff Schedule of the United States is subdivided by chromic oxide content as follows: containing not more than 40% chromic oxide; containing more than 40% and less than 46% chromic oxide; and containing 46% or more chromic oxide. Chromite producers typically specify the following: chromic oxide content, chromium-to-iron ratio, and iron, silica, alumina, magnesia, and phosphorus contents. Size also is specified for some applications. The chromic oxide content of chromite ranges from 36% to 56%, with values in the 40% to 50% range most common. Chromium-to-iron ratios range from about 1.5:1.0 to about 4.0:1.0, with typical values of about 1.5:1.0 to 3.0:1.0.

The import category of chromium ferroalloys is divided into ferrochromium and ferrochromium-silicon. Ferrochromium-silicon, also called ferrosilicon-chromium and chromium silicide, is not classified further. Ferrochromium is classified by its carbon content as follows: containing not more than 0.5% carbon; containing more than 0.5% carbon but not more than 3% carbon; containing more than

* Blank cells indicate that producer does not provide specs for more than one grade.

† na = not available.

‡ max = maximum.

§ min = minimum.

3% but not more than 4% carbon; and containing more than 4% carbon. Producers classify their material as low- or high-carbon or charge-grade ferrochromium (also known as *charge chrome*). Sometimes the terms *medium-carbon* and *extra-low carbon ferrochromium* are used. Low-carbon ferrochromium contains less than 4% carbon; high-carbon contains more than 4% carbon. Producers of chromium ferroalloys specify chromium, carbon, silicon, phosphorus, and sulfur content, as well as material size. Ferrochromium-silicon typically contains 24% to 40% chromium; 38% to 50% silicon; and 0.05% to 0.1% carbon. Ferrochromium typically contains 50% to 75% chromium and 0.05% to 8% carbon. Low-carbon ferrochromium typically contains 55% to 75% chromium and 0.02% to 0.1% carbon. High-carbon ferrochromium typically contains 60% to 70% chromium and 6% to 8% carbon. Charge-grade ferrochromium typically contains 50% to 55% chromium and 6% to 8% carbon.

The Steel Founders' Society of America (1967) suggested specifications for chromite sand, used primarily as either molding sand or as core sand in the production of steel castings, and chromite flour, an additive to chromite sand. Among other requirements, they describe chemical composition as 44% Cr₂O₃ (minimum); 26% FeO (maximum); 3% SiO₂ (maximum); 1% CaO (maximum); and Al₂O₃, MgO, and trace elements as the balance.

By-products and Coproducts

By-product or coproduct here means a mineral product that is different from the primary product and not different grades of the primary mineral product. No by-products or coproducts are associated with chromite ore mining operations. A chromite ore mining operation is likely to produce more than one grade of chromite. These grades are distinguished by size and chemistry. In the Bushveld Complex, MINTEK (South Africa's mining research organization) demonstrated the feasibility of recovering platinum from the LG-6 chromitite layer mineralizings; there is, however, no commercial recovery.

Platinum has been mined from the Merensky Reef, a chromite-free seam of the Bushveld Complex. As platinum reserves are depleted, platinum mining is moving to the chromite-containing UG-2 seam. Chromite-containing tailings are produced when UG-2 ore is processed to recover platinum. Since MINTEK demonstrated ferrochromium production from UG-2 platinum mine chromite by-product, South African smelters have adapted their processes and furnaces to accommodate that material.

USES

The ICDA (2003) reports world production of chromite by end use sector, and categorizes them as chemical, foundry sand, metallurgical, and refractory. From 1998 through 2002, ICDA reported chromite use as 90% metallurgical, 6% chemical, 3% foundry sand, and 1% refractory. These account for an average demand of 15 Mtpy gross weight of chromite, which is equivalent to about 4.3 Mtpy chromium content.

U.S. chromium demand from 1998 to 2002 is estimated to have averaged about 463,000 tpy of chromium, based on chromium content in chromite; chromium chemicals, ferroalloys, and metal; and stainless steel scrap. For that time period, about 88% of U.S. average chromium consumption per year was in the metallurgical industry, 12% in the chemical industry, and <1% in the refractory industry. About 75% of metallurgical domestic apparent consumption went into stainless steel based on reported consumption of chromium ferroalloys and metal. Refractory chromite use was most likely greater than that estimated here, because it is based on reported consumption of chromite by the refractory industry and not consumption of refrac-

tory materials. Foundry sand has never been included in refractory chromite consumption. Material categories for the purpose of monitoring trade do not differentiate among chromite end uses nor do they differentiate chromium-containing refractories from other refractories. Consequently, domestic chromite use and chromium-containing refractory use cannot be accurately tracked using trade statistics. Figure 5 shows material flow associated with the use of chromite materials and illustrates the relationships between industrial and metallurgical uses of chromium materials. (Chromium consumption differs from chromite consumption because chromium consumption includes chromite and chromium chemicals, ferroalloys, and metal, whereas chromite consumption includes only chromite.)

Chromite Uses

The metallurgical industry processes chromite into ferrochromium or chromium metal, which are used as alloying materials to make a variety of ferrous and nonferrous alloys. The major end use is stainless steel, a ferrous alloy made resistant to oxidation and corrosion by the addition of chromium. The chemical industry uses chromite to make sodium dichromate, which is a chemical industry product and an intermediate product used for making other chromium chemicals. Chromium chemicals find a wide variety of end uses such as leather tanning, pigments, plating for both decorative and engineering applications, surface treatment of reactive metals, and manufacture of chromium metal, a key ingredient in alloys for aircraft engines and land-based turbines. Chromite is useful in the foundry and refractory industries because it retains its physical properties at high temperatures and is chemically inert. Chromite is used as facing sand in the foundry industry, and the refractory industry uses chromite to produce refractory materials, including shapes, plastics, and gunning mixes. Refractory materials are used in the production of ferrous and nonferrous alloys, glass, and cement.

Chromite Consumption in the United States

U.S. chromite consumption was reported from 1940 through 1994; after 1994, data could not be kept confidential because of the small number of consuming companies. Figure 6 shows reported consumption by industry (i.e., chemical, metallurgical, and refractory), total reported consumption, and net imports of chromite. Net imports of chromite exceeded total reported consumption before 1965, the time during which the U.S. federal government was building the NDS. At its peak in 1962, the NDS contained 7.92 Mt of chromite. Since 1994, chromite consumption by metallurgical and refractory industries ended and virtually all U.S. chromite consumption is now by the chemical industry.

Based on net chromite imports, U.S. chromite consumption averaged 145,000 tpy from 1998 through 2002, a decline from the 1940 through 1997 average of 927,000 tpy. The decline occurred when domestic chromite users shifted from domestic to foreign ferrochromium suppliers for the metallurgical industry.

Figure 6 shows an increase in U.S. chromite use from 1940 to the mid-1950s, a period coinciding with increased consumption in the metallurgical industry. Between 1939, when NDS legislation was passed, and 1961, when NDS chromite inventories were made public, accumulated domestic chromite production (measured as reported shipments) plus net trade in excess of reported consumption amounted to 7.1 Mt and the NDS inventory amounted to 6.7 Mt. Attributing all the difference to reported chromite use suggests unaccounted-for consumption was <3% (of accumulated reported consumption) from 1940 through 1961.

The largest changes in reported consumption were in the metallurgical and refractory industries. Chemical industry use

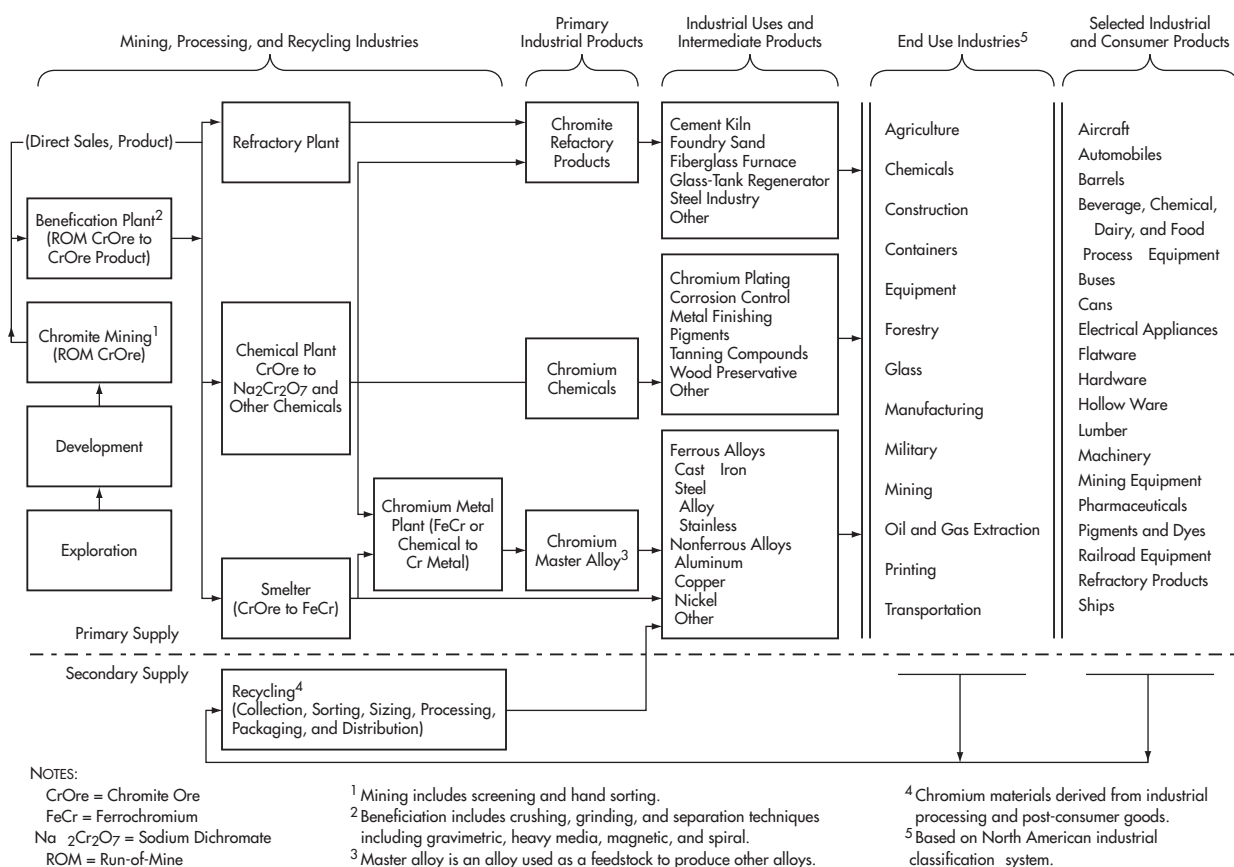

Figure 5. Chromium material flow from chromite ore mining to end use

increased slowly from 1940 to 2002. Refractory industry use reached a plateau from about 1950 to 1965, after which it slowly declined. Metallurgical industry chromite use increased from 1940 to the mid-1960s, after which it declined to nothing. Coinciding with the drop in metallurgical use, chemical use increased its share of the U.S. market. Declining metallurgical industry use resulted from declining domestic ferrochromium production. From 1940 through 1985, the metallurgical, chemical, and refractory industries data were reported separately: the metallurgical industry accounted for 56% of reported total chromite consumption; the refractory industry, 27%; and the chemical industry, 18%. After 1985 the amount of chromite consumed by various industries remains unknown because chromite end use cannot be inferred reliably from trade data.

Metallurgical Industry

Figure 6 shows metallurgical industry chromite consumption, and Figure 7 shows its chromite market share. The metallurgical industry dominated domestic chromite consumption from 1940 to 1980. The patterns of total chromite consumption and net imports match those for metallurgical consumption over that period. With the dramatic drop in metallurgical consumption of chromite from 1980 to 1983, chemical industry consumption surpassed metallurgical consumption for the first time since record keeping started in 1940.

In the metallurgical industry, chromite is used to make ferrochromium, which is used to make steel and nonferrous alloys. Ferrochromium is produced from chromite ore in an electric-arc furnace using reductants and fluxes to remove oxygen. Ferrochromium

Figure 8. Major chromium chemicals and their end uses

high-carbon ferrochromium at its Charleston, South Carolina, plant in 1998. Since 1941 ferrochromium was produced at the Charleston plant site, which was built as part of the World War II mobilization effort. It was located to take advantage of access to ocean-going transportation. The Santee Cooper Project, a public power supply project there, provided electrical power. During the war Pittsburgh Metallurgical Corp. manufactured ferrochromium, a key ingredient in armor plating for tanks and ships.

The Charleston plant operated under a variety of names (in chronological order): Pittsburgh Metallurgical Corp., Airco Alloys Division, Air Reduction Co., Inc.; Airco Alloys and Carbide Division, Air Reduction Co., Inc.; Airco Alloys, Air Reduction Co., Inc.; and Airco Alloys, Airco Inc. Macalloy Corp. had operated the plant since 1980; 8 chromium ferroalloy producers in the United States were operating 12 plants in 1980.

Chemical Industry

Chromite has been the key raw material in the manufacture of chromium chemicals since the early 19th century, initially to make brightly colored pigments. Today, production includes biocides, catalysts, corrosion inhibitors, metal plating and finishing chemicals, oil field chemicals, pigments, printing chemicals, tanning compounds, and high-purity chromium metal. The largest single use of chromium chemicals today is the use of chromium salts in the manufacture of leather from animal skins, a process which began in the middle of the 19th century. Chromium plating is the electrodeposition of chromium from a solution of chromic acid; it was started in the early 1900s. A recent use for chromium is for wood preservation. Chromium-copper-arsenate (CCA) impregnates wood to protect it from weathering, insects, and decay for up to 30 years. Major chromium chemical plants are in Japan, Kazakhstan, Russia, South Africa, the United Kingdom, and the United States; only Kazakhstan and South Africa, however, are significant chromite producers. Sodium dichromate and chromic acid accounted for the largest amount of U.S. chromium chemical exports and imports, respectively.

The terms *chromium* and *chrome* are synonymous in the chemical industry for elemental chromium. Historically, the term *chrome* was used more commonly than *chromium*; thus, many chemical products (namely pigments) have “chrome” in their name. The terms *bichromate* and *dichromate* are interchangeable in the chemical industry. Dichromate is consistent with the convention for naming compounds; the term *bichromate*, however, also is used in trade and commerce.

Sodium dichromate, an intermediate chemical produced from chromite, is used to manufacture other chromium chemicals. The process involves pulverizing chromite and mixing it with soda ash (sodium carbonate; Na_2CO_3) and a diluent. Historically, the diluent was lime (calcium oxide; CaO), limestone (calcium carbonate; CaCO_3), or dolomite (calcium magnesium carbonate; $\text{CaMg}(\text{CO}_3)_2$); today, however, the “high-lime” process accounts for about one half the global chromium chemical production capacity, mainly in China, the CIS, and India. Around 1960, western producers had developed “zero lime” or “very low lime” processes in which the diluent was recycled material from production processes. The chromite- Na_2CO_3 -diluent mixture is roasted in a rotary kiln to produce a compound containing sodium chromate, which is leached and treated with acid to produce sodium dichromate prior to purification. This process is used in United States. Sodium dichromate dihydrate is the first commercial product made when converting chromite into chromium chemicals; it is the commercial product produced and traded most. Many other chromium chemicals are manufactured from sodium dichromate (Figure 8). In 2002, more than one-half of

chromium chemical production came from no-lime processes (54%); 0.5%, from low-lime processes; and the remainder from lime processes that used dolomite or limestone.

The use of chromium chemicals for pigments is a familiar use to many people. Medium yellow pigment, a lead-chromate compound, is used in yellow paint for traffic control on major streets and highways. Copper-chrome pigment is used in the black coating on outdoor grills and wood-burning stoves. Chromium pigments are important in anticorrosion coatings; the U.S. military and the federal government are major users of chromate metal primers. Chromium oxide is a green pigment used in camouflage because it is efficient in reflecting infrared wavelengths.

China has the largest overall chromium chemical production capacity; Chinese plants, however, have only small production capacities (<50,000 tpy of sodium dichromate). The largest chromium chemical plants (>100,000 tpy of sodium dichromate) are in Kazakhstan, Russia, the United States, and the United Kingdom. An intermediate size plant (between 50,000 and 100,000 tpy of sodium dichromate) in South Africa is the newest chromium chemical plant. The United States is a major consumer, producer, and supplier of chromium chemicals. Table 4 shows chromium chemical production capacity by country and year. Worldwide production capacity in 2002 was about 299,000 t contained chromium, or about 855,000 t sodium dichromate dihydrate equivalents. Many small chromium chemical plants are located in chromite-producing countries. Industry rationalization in developed countries has replaced small plants with larger, more efficient ones operated to higher occupational safety and environmental standards. For example, the number of chromium chemical plants in Europe and the United States decreased from 17 to 2 in the past 40 years. The opposite occurred in China, where chromium chemical production began in the 1950s, with more than 20 plants operating today. China's policy today is to modernize chromium chemical production and to reduce the number of small plants.

Figure 9 shows domestic production of major chromium chemicals: sodium dichromate, chromic acid, and chromium pigments. Sodium dichromate production was reported until 1985, when production was about 120,000 t. Chromium pigment production declined from >50,000 tpy in the mid-1970s to <10,000 tpy in 1996, the last year the U.S. Department of Commerce reported such production. Chromic acid production was about 27,000 tpy in 1973, the last year it was reported (Anon., various years). In Figure 9, chromium pigment production is shown as a composite of the production of several chromium pigments. Chromium pigment production in Figure 10 includes chrome yellow and orange, chrome molybdate orange, chrome oxide green, zinc yellow, and chrome green. The greatest production is for chrome yellow and orange followed by chrome molybdate orange. For both, production peaked in the mid-1970s. Chrome yellow and orange annual production declined from about 34,000 to <5,000 t when production was last reported in 1997. The chrome molybdate orange production series was discontinued in 1987. Zinc yellow annual production peaked between 1965 and 1967; the series was discontinued in 1987. Zinc yellow production data were withheld from 1976 to 1985. The decline in chromium pigment manufacture is associated with pigments that contain hexavalent chromium. Use of hexavalent chromium pigments declined because of increased awareness of health and environmental hazards associated with hexavalent chromium compounds, and the availability of less hazardous alternatives. The reporting of chrome oxide green production data was discontinued in 1985; chrome green production data were no longer reported after 1972. Chrome oxide green is trivalent; chrome green is a mixture of hexavalent chromium compounds.

Table 4. Chromium chemical production capacity (in kilotons of chromium per year)

Figure 9. U.S. chromium chemical production by material (sodium chromate and sodium dichromate, chromic acid, and chromium-containing pigments). (The dotted line segment indicates linearly interpolated data.)

Figure 11 shows the number of producers of the following chromium chemicals: sodium dichromate and chromate, chrome yellow and orange, and chrome molybdate orange. Figures 10 and 11 show the decline in both production of chromium pigments and the number of producers. The number of sodium dichromate and chromate producers has also declined; production did not decline, however, suggesting that production was consolidated by the remaining two producers in 1990. The general trend of reported production (Figures 9 and 10) appears to be consistent with that of chromite consumption (Figures 6 and 7).

Courtesy of USGS and U.S. Census Bureau.

Figure 10. U.S. chromium pigment production by pigment (chrome green, chrome molybdate orange, chromic oxide green, chrome yellow and orange, and zinc yellow). (The dotted lines that connect the chrome yellow and orange, chrome molybdate orange, and zinc yellow data curves are linearly interpolated.)

Figure 11. Number of U.S. chromium chemical and pigment producers, by product

A review of the world chemical industry in 2001 (Darrie 2001; Tomkinson and Moore 2001) characterized the industry as mature and growing slowly. Access to modern technology, capital investment in new plants and equipment, and excess production capacity were barriers to market entry. Pressure from competition and environmental regulation forced producers to consolidate. These factors were expected to reduce the number of producers and limit production to large plants. Global demand in 2000 was estimated at 692,000 t (sodium dichromate equivalent) of which 32% went into chromic acid; 34%, chromium sulfate; 20%, chromic oxide; and 14%, other uses. Chromic acid was used for metal finishing (50%), timber treatment (35%), magnetic media (5%), and other uses (10%). Chromium sulfate was used for leather tanning. Chromic oxides were used for pigments (47%), the manufacture of

chromium metal for alloys (33%), ceramics (8%), and other uses (12%).

CCA was a popular wood treatment chemical in the United States. It was the second largest worldwide market for chromic acid, the major product from sodium dichromate, accounting for about 78,400 t of chromic acid in 2000. The United States accounted for about one half the global CCA market, of which about three quarters was used to treat wood for residential applications. In 2002 U.S. manufacturers of treated wood planned to phase out CCA use by voluntary agreement with the U.S. Environmental Protection Agency (EPA). EPA banned CCA use for residential applications under the Federal Insecticide, Fungicide, and Rodenticide Act (EPA 2002). As a result, U.S. chemical industry chromium consumption was expected to drop between 2002 and 2004 and cause the U.S. chromium chemical industry to reorganize.

In 2002 the chemical industry worldwide consumed about 1 Mtpy of chromite to produce 692,000 t of sodium dichromate. Sodium dichromate was converted to chromic acid at the rate of 224,000 tpy. Chromic acid accounted for 32% of sodium dichromate demand; chromium sulfate, 30%; chromic oxide, 20%; and other chemicals, 18%. Chromic acid was converted to CCA at the rate of 100,000 tpy. CCA accounted for 35% of chromic acid demand; metal finishing, 50%; magnetic media, 5%; and other uses, 10%.

Since 1967, when five chromium chemical plants owned by four companies consumed chromite to produce sodium dichromate in the United States, the number of U.S. chromium chemical plants has been declining, whereas chromium chemical production has been slowly increasing. Rationalization of the U.S. chromium chemical industry left one plant producing chromium chemicals from chromite in 2002.

Refractory Industry

Chromite is used directly in the refractory industry because it resists degradation when exposed to heat. Chromic oxide, a chemical industry product, also is used in refractory applications. Basic refractories are a type of nonclay refractory that behave chemically as bases. Basic refractories are made of chromite, dolomite, magnesite, or various combinations of magnesite and chromite. In the refractory industry, chromite-containing refractories are called *chrome refractories*. Chrome-magnesite refractories contain more chromite than magnesite; magnesite-chrome refractories contain more magnesite than chromite.

Refractories also are categorized as shaped or unshaped. Shaped refractories are manufactured to fit together, like building blocks, to form a desired geometric structure. Unshaped refractories include mortars (materials used to bind shaped refractories together), plastics (materials that are formed into a desired shape), and gunning (material that is sprayed onto a surface). In the refractory industry, the term *monolithics* describes refractories that are not shaped. Units for reporting shipments of shaped and unshaped refractories differ. Shaped refractories have been reported in thousand "9-in. brick" equivalents, and unshaped refractories have been reported in metric tons based on U.S. Department of Commerce reports (Anon., various years). A 9-in. brick equivalent (9be) is a solid volume of 0.165919 m³.

Major end users for chromite refractories are in the cement, copper, glass, nickel, and steel industries. Basic refractories are used in copper and nickel furnaces. The glass industry uses chromite refractories in glass tank regenerators; the cement industry uses chromite refractories primarily in transition zones of cement kilns. Basic refractories typically have been used in open hearth and electric arc steelmaking furnaces.

Contemporary steelmaking processes using the basic oxygen furnace or the electric arc furnace use much less chromite-containing refractories than open-hearth furnaces. Open-hearth furnaces used about 30 kg of refractories per ton of steel, the basic oxygen furnace uses about 1 kg/t, and the electric arc furnace uses from 1 to 2 kg/t. Steel industry demand for basic refractories has declined dramatically as open-hearth furnace steelmaking is phased out. Chromite use in cement kiln refractories has declined owing to hexavalent chromium mobilization. The introduction of technically acceptable substitutes has eliminated chromite refractories in cement kilns. Recycling chromite refractory brick in the cement industry was discontinued in the 1990s.

Figures 12 through 14 show historical trends of chromite refractory shipments. Chrome and chrome-magnesite refractories represent at least one-half the chromite consumed in refractories. The ASTM promulgates specifications for the identification of chrome, chrome-magnesite, and magnesite-chrome brick. Chrome brick is refractory brick manufactured substantially or entirely of chromite product. Chrome-magnesite and magnesite-chrome brick are classified by magnesia (MgO) content. Nominal MgO content is from 30% to 80%, therefore the chromite content is more than 20%. The amount of chromite in magnesite and magnesite-chrome refractories is unknown.

Because chromite represents only a part of the refractory industry, one can only infer the performance of chromite refractories from shipment data for basic unshaped refractories. This is because the data include other refractory materials such as dolomite, forsterite, magnesite, and zircon.

Figure 12 shows shipments of chromite-containing shaped refractories. Chrome and chrome-magnesite refractory shipments declined from 1960 through 1981 (Figure 14; the data series was discontinued in 1981). The number of chrome and chrome-magnesite refractory producers fell from nine to seven during that same time period. Since 1981, the number of chromite refractory producers has fallen from seven to zero because of declining demand. Magnesite and magnesite-chrome refractory shipments grew from 1960 through 1965 (Figures 12 and 14), after which large variations occurred. From 1982 through 1990 magnesite-chrome refractory shipments decreased from 28 to 18 M9be (Figure 12). The U.S. Department of Commerce reported chrome and chrome-magnesite shipments, whereas magnesite and magnesite-chrome, and magnesite-chrome shipments data are a composite of reported shipments.

Figure 13 shows U.S. shipments of chromite-containing unshaped refractories. Mortar shipments declined rapidly from 1964 to 1970, and then very slowly decreased until 1986, when they were no longer reported. Plastic and gunning shipments show a slow decline.

Figure 14 shows refractory shipments for magnesite and magnesite-chrome (1960 to 1981) and magnesite-chrome (1982 to 1997). Magnesite and magnesite-chrome shaped refractory shipments were reported as such and represent the 1960 through 1970 time period in Figure 14. From 1971 through 1981, magnesite and magnesite-chrome shaped refractory shipments were reported as pitch bonded, pitch impregnated, or other (Figure 12). These three categories were combined to form the magnesite and magnesite-chrome shaped refractory shipments curve for the 1971 through 1981 time period in Figures 12 and 14. From 1982 through 1990, magnesite and magnesite-chrome refractory shipments were reported as high-fired magnesite-chrome, except high-fired magnesite-chrome, and magnesite and magnesite-carbon refractories (not shown). Starting in 1982, magnesite-chrome was reported separately from other magnesite refractory shipments. From 1982 through 1990, magnesite-chrome shaped refractory shipments were

reported as high-fired and except high-fired (Figure 12), forming the magnesite-chrome shaped refractory shipments curves for the 1982 through 1990 time period shown in Figures 12 and 14.

Because the chromite-containing magnesite refractories data were separate from the chromite-free magnesite refractories data beginning in 1982, the fraction of magnesite and magnesite-chrome refractory shipments that contain chromite can be calculated for the 1982 through 1990 time period. By volume, magnesite-chrome refractory shipments averaged 50% (ranging between 41 % and 57%) of magnesite and magnesite-chrome refractory shipments from 1982 through 1990.

Beginning in 1985, shapes were reported in tons also. From 1985 through 1990, the weight per volume of magnesite-chrome refractories averaged 4,700 t/M9be with a range of from 4,300 to 5,000 t/M9be.

Chromic oxide, a chemical industry product, also is used to make refractories for the glass industry. Chromic oxide refractories are used in contact areas of glass melting furnaces to achieve long furnace life.

The general decline in refractory use resulted, in part, from more efficient use of refractories. Use of longer-lasting refractories decreases downtime associated with replacing spent materials, which consequently lowers labor costs and increases production (less time for relining equipment). The decline in chromite-containing refractory use is directly related to the cessation of open-hearth steelmaking in the United States.

EPA regulation of waste chromium significantly affected chromite refractory use (discussed under the Environmental Regulations section).

To protect company proprietary data, the USGS discontinued reporting chromite consumption by the refractory industry when the number of reporting producers fell to three in 1994. Chromite-containing refractory production in the United States was virtually zero in 2002; U.S. consumers today rely on imports. Because the amount of domestic chromite-containing refractory production is no longer reported, and because trade data are inadequate to track consumption, it is no longer possible to quantitatively characterize the industry using publicly available statistics.

Foundry Sand

Foundry sand forms the mold in which molten metal is contained until the metal solidifies in the desired shape. The sand is washed, graded, and dried beforehand. Because silica sand is refractory, common, and inexpensive, it is the most widely used mineral for foundry sand; other sands (e.g., zircon, olivine, or chromite) may be chosen, however, depending on physical or chemical conditions. The use of chromite foundry sand is a modern development. Chromite foundry sand is used in the ferrous and copper casting industries.

Courtesy of USGS.

Figure 15. U.S. chromite production

Chromite sand is compatible with steel castings. It is typically used as facing sand in heavy section (greater than 4 t) casting and enjoys a technical advantage over silica sand in casting austenitic manganese steel (chromite sand does not react with the manganese in steel). Because chromite and zirconia have higher melting temperatures than silica, they are chosen when casting temperatures exceed those acceptable for silica sand. Table 5 shows U.S. foundry sand producers, products, and end uses.

Chromite sand casting was developed in South Africa where chromite fines are readily available as an inexpensive grade of chromite. After successful results in South Africa in the late 1950s, use expanded into the 1960s in the United Kingdom and closely thereafter in the United States. Initial use of chromite sand coincided with a shortage of zircon sand; chromite sand had the additional advantage of being an inexpensive substitute. Foundry characteristics that make chromite sand desirable are good thermal stability, good chill properties, not easily wetted, resistant to metal penetration, highly refractory, and chemically nonreactive. Compared with zircon sand, the disadvantages of chromite are higher thermal expansion, occasional presence of hydrous mineral impurities, and different bonding characteristics with some binding agents.

As much as 90% of chemically bonded foundry sand (average of minerals used) can be reclaimed (Heine 1989) using mechanical, pneumatic, wet, or thermal processes, or combinations of them. These processes have been adapted to chromite sand. After casting, chromite sand, typically used as facing sand, is mixed with bulk sand (silica). Because the size distribution of chromite sand is similar to that of silica sand, mechanical methods cannot separate them sufficiently; hydraulic spiral separation and magnetic separation, however, effectively separate chromite sand from silica and zircon sands (silica and zircon sands are nonmagnetic). Some chromite sand degrades and then tends to adhere to castings, so it is not part of the reclaimed sand. Reclaimed chromite sand is indistinguishable from new chromite sand. Sontz (1972) estimated that about one-half the foundry industry chromite demand could be met with reclaimed chromite sand.

The USGS does not survey for chromite-containing foundry sand consumption, and the Harmonized Tariff Schedule of the United States does not clearly identify such material in trade; therefore, no statistics are publicly available with which to characterize the U.S. industry.

Table 6. Chromite world production by country, 1994–2004 (in metric tons, gross weight of chromite product)

ECONOMIC FACTORS

Production, Consumption, and Trade

Chromite currently is not produced in the United States. Russia was the original source of chromite in the 1700s and was the major world supplier into the nineteenth century. During the 1800s, chromite was discovered and mined in Maryland, Pennsylvania, and later, California. The United States then became a major producer of chromite ore. Chromite mined in Maryland and Pennsylvania fed the first U.S. chromium chemical plant at Baltimore, Maryland. Chromite was then discovered in Turkey, which soon dominated world production. U.S. production peaked during times of major conflict (e.g., World Wars I and II and then declined until commercial production ended, although some noncommercial production continued sporadically into the 1960s (Figure 15). The figure shows events significant to U.S. industry, including World War I (1914–1918); NDS acquisition enabling legislation (1939); World War II (1939–1945); and the Korean War (1950–1953).

Since 2000, India, South Africa, and Kazakhstan have been the leading producers of chromite. Table 6 shows chromite production by country. Figure 16 shows world chromite production and U.S. chromite consumption. The figure shows the same events as in Figure 15 significant to world industry or U.S. industry, adding the Vietnam War (1961–1975); oil embargo (1973); catalytic converter use adopted in the United States (1975); dissolution of the U.S.S.R. (1991); closure of the last U.S. high-carbon ferrochromium plant; and discontinued use of FCCA to treat wood for domestic use.

Courtesy of USGS.

Figure 16. World chromite production and U.S. chromite reported consumption and net imports. U.S. net chromite imports are shown as a dotted line; reported chromite consumption, as a solid line.

World chromite production declined significantly beginning in 1940 through 1945, from 1978 through 1983, and from 1990 through 1993. The United States dominated world chromite consumption from 1945 through 1948. World chromite production has grown since then, whereas U.S. chromite consumption declined

Figure 17. World chromite production by country (1998–2002 average). The bar chart shows the countries with smaller production on a smaller scale so that their relative production is apparent.

Figure 18. World ferrochromium production by country (1998–2002 average). The bar chart shows the countries with smaller production on a smaller scale so that their relative production is apparent.

between the 1950 and 1970 average. Reduced U.S. chromite consumption beginning about 1970 resulted primarily from the replacement of chromite by ferrochromium as a source of chromium units for the domestic metallurgical industry and, secondarily, from declining use of chromite by the domestic refractory industry. Since 2002, reduced demand for chromite by the chemical industry also contributed to the decline.

The United States continues to be a major consumer of chromium; it now gets chromium units via downstream products such as ferrochromium, chromium chemicals and metal, and stainless steel scrap, however, rather than from chromite. U.S. annual chromium consumption is equivalent to about 12% of annual world chromite production.

Since 2000, three major chromite producers (India, Kazakhstan, and South Africa) were producing consistently more than 1 Mtpy each. They accounted for about 80% of annual world production, and South Africa accounted for nearly one-half of world production. Seven other significant chromite producers have annual production ranging from 100,000 t to 1 Mt: Albania, Australia, Brazil, China, Finland, Turkey, and Zimbabwe. These seven accounted for more than 15% of annual world production (see Table 6 and Figure 17).

Chromite is consumed mostly by steel, chemical, and refractory industries located in developed countries. Historically, chromite ore was mined, exported, processed, and then consumed; chromite-producing countries, however, are developing the vertical integration of their chromium industries. For example, South Africa increased the number of ferrochromium plants, integrated chromite mining and ferrochromium operations, restarted chromium chemical production (in 1999), and significantly increased stainless steel production. Kazakhstan began chromium metal production with a process that requires chromic oxide, a chemical industry product, as feed material. Thus it sustains an existing industry (chromium chemicals) and enters a new product area (chromium metal). Kazakhstan rebuilt its ferrochromium industry and marketed its ferrochromium in Asia, Europe, and the United States after the dissolution of the Soviet Union in 1991 resulted in reduced demand for its product. Since about 1970, ferrochromium production has shifted from areas that historically had produced stainless steel (i.e., Japan, the United States, and Western Europe) to chromite-producing countries. Finland, India, Kazakhstan, and South Africa are the only chromium-consuming countries not dependent on imports of chromite or chromium. The development of ferrochromium production in chromite-producing countries has reduced international trade of chromite. South Africa continues to build ferrochromium production and capacity, and Japan and Western Europe retain marginal production capacity (see Figures 18 and 19).

Prices

Chromite, ferrochromium, and chromium metal are not traded in open market exchanges like gold, silver, nickel, and other metals. The price of chromite usually is negotiated between buyer and seller. Some trade publications survey chromite sellers and buyers and report a calculated composite price. Included among these are *Platts Metals Week* (<http://www.platts.com/Metals>), *Metal Bulletin* (<http://www.metalbulletin.com>), *Industrial Minerals* (<http://www.indmin.com/index.html>), and *Ryan's Notes* (<http://www.ryansnotes.com>). Unfortunately, the volume of trade is unknown.

When the United States imports materials, the invoice value is declared at the port of export. This is called the f.o.b. (free on board) value. Figure 20 shows the mass-weighted average declared f.o.b. actual value of U.S. chromium imports (averaged over all grades). The price of chromite from important chromite suppliers (South Africa and Turkey) as reported in trade journals is shown along with the import value. The upper price lines are typically for Turkish chromite; the lower price lines are typically for South African chromite. Import values closer to the lower prices reflect the fact that South African chromite was imported in greater quantities than was Turkish chromite. Figure 20 shows that the value of U.S. chromite imports and the reported prices have similar trends over time. Figure 21 shows the same values and prices in Figure 20

Source: USGS; U.S. Census Bureau; *Engineering and Mining Journal*; *Platts Metals Week*; *Ryan's Notes*; *Industrial Minerals*.

Figure 20. U.S. chromite actual value (based on import statistics) and price (as reported in trade journals). Price histories from various sources are shown as narrow gray lines; value history based on all grades of chromite imports is shown as a broad dark line. Value history is mass-weighted average value over all grades.

adjusted for inflation and normalized to 1998 dollars. Chromite declined in real value but increased in actual dollars.

Figure 22 shows the actual value of chromite by grade. Unit values are given in dollars per metric ton, gross weight of chromite based on declared f.o.b. values. Figure 22 also shows the unit value of each import grade and the mass-weighted average over all grades, which is called the *import value*. In the latter part of the time period (20th century), unit values by grade differ from import value significantly more than they did earlier. Although not obvious in Figure 22, when unit values deviate significantly from the import value, the import value very closely approximates imports of 40% to 46% Cr_2O_3 grade chromite (the dominant imported grade after 1991). Significantly deviant values are thought to result from specialty items that have high unit value but are relatively low in volume (measured in tons of material imported). When these are averaged with bulk materials, the bulk materials value tends to dominate. High values of less than 40% Cr_2O_3 and 40% to 46% Cr_2O_3 grades after 1990 result from declining bulk imports of those grades, so that these categories are represented by small volume-high price, specialty materials. The figure illustrates that high-unit-value chromite at the end of the time period shown was small in quantity.

The value of chromite was relatively stable through 1970, when it started to rise. Chromite value declined from 1982 to 1988, when steel production in general and stainless steel production in particular was weak. Stainless steel recovery from 1988 through 1990 resulted in a short supply of ferrochromium that nearly doubled the price of ferrochromium and stimulated an expansion of capacity in the industry, primarily in South Africa. The price of chromite also rose as a result. Chromite production capacity was added to meet an anticipated demand from increased ferrochromium production capacity, primarily in South Africa and India.

Availability

The U.S. Bureau of Mines studied the availability of chromium in 10 market economy countries (MECs) (Boyle, Shields, and Wagner 1993). The analyzed for the simultaneous availability of chromium contained in chromium ferroalloy products and in exportable

Figure 22. U.S. value of chromite by grade (<40% Cr_2O_3 , 40% to 46% Cr_2O_3 , >46% Cr_2O_3 , and mass-weighted average over all grades) and by year. The narrow gray lines represent linearly interpolated values for <40% Cr_2O_3 and 40% to 46% Cr_2O_3 grades that replace values >\$200 per ton for 1999–2001. Although not graphed, these values were included in the average over all grades.

chromite products (metallurgical, chemical, refractory, and foundry sand).

In the same work, the author assessed about 874 Mt gross weight of in situ material containing about 203 Mt of chromium. Extraction and beneficiation of this material was estimated to result in about 475 Mt of chromite products, of which 289 Mt would be available for export and the remaining 186 Mt would be smelted in the countries in which it was mined to produce about 80 Mt of chromium ferroalloys. The chromium ferroalloys would then be available for use in the countries of production or for export. The 80 Mt of chromium ferroalloy included about 74 Mt of high-carbon ferrochromium, 4 Mt of low-carbon ferrochromium, and 2 Mt of ferrochromium-silicon.

Table 7. Availability of chromite and chromium ferroalloys from 10 market economy countries

Chromium Materials	Quantity Available, Mt gross wt	Cost,* \$/t		
		Weighted Range		
		Average	Low	High
Chromite				
Chemical grade	64.3	53	35	174
Foundry sand grade	16.4	49	39	83
Metallurgical grade				
Primary product	145.4	101	42	705
Secondary product	35.6	54	33	117
Subtotal	181.0	92	33	705
Refractory grade	26.8	87	54	180
Total	288.5			
Chromium ferroalloys				
Ferrochromium				
High-carbon ferrochromium	74.3	473	417	1,286
Low-carbon ferrochromium	3.9	937	635	1,309
Ferrochromium-silicon	2.0	737	578	814
Total	80.2			

* Price required for 0% discounted cash flow rate of return in January 1989 dollars per metric ton, gross weight, of product.

South Africa and Zimbabwe hosted about 80% of the contained chromium in situ. India and Finland accounted for an additional 11% of the contained chromium; another 8% of the contained chromium was divided evenly among Brazil, the Philippines, Turkey, and the United States; the remainder was in Greece and Madagascar.

Based on Cr₂O₃ content of in situ chromite ore, the 10 MECs fit into 2 groups. The high-grade group (ore grades ranging from 33.96% to 43.01% Cr₂O₃) included India, Madagascar, South Africa, Turkey, and Zimbabwe. The low-grade group (ore grades ranging from 9.16% to 26.65% Cr₂O₃) included Brazil, Finland, Greece, the Philippines, and the United States. The high-grade group averaged 38.76% Cr₂O₃ and the low-grade group averaged only 15.90% Cr₂O₃.

Table 7 shows the results of the Boyle, Shields, and Wagner (1993) analysis. Chromium material costs were calculated on a weighted average basis, f.o.b. ship at port of export. The chromite cost shown covers mining and beneficiation of the ore (including capital costs at the mine, operating costs, and taxes) and transportation of ore and products to port facilities. Chromium ferroalloy cost includes chromite, but excludes smelter capital cost. On a weight basis, the analysis shows that South Africa and Zimbabwe could produce the following at their respective estimated breakeven costs: about 78% of metallurgical chromite, 93% of chemical chromite, 85% of refractory chromite, and 93% of foundry chromite. South Africa and Zimbabwe also could produce the following at their respective estimated breakeven costs: about 69% of the high-carbon ferrochromium; 89% of the low-carbon ferrochromium; and 100% of ferrochromium-silicon. The product breakdown between chromium ferroalloy and chromite, and among the grades within those product categories, was based on mine and smelter production capacities and known operating relationships for 1987 through 1988.

GOVERNMENT CONSIDERATIONS

Strategic Factors, Stockpile

The U.S. government has maintained the NDS in the event of a national defense emergency since 1939. The DLA is currently

responsible for the NDS. The Strategic and Critical Materials Stock Piling Act (50 U.S.C., section 98 *et seq.*) mandates that a stockpile of strategic and critical materials be maintained to decrease and preclude, where possible, dependence on foreign sources of supply in times of national emergency. The NDS was intended to provide raw materials to industry while mine production capacity was being increased, thereby reducing the amount of time needed to mobilize the domestic economy. Chromium materials that were included in the NDS are chromite (metallurgical, chemical, and refractory grades), chromium ferroalloys (high- and low-carbon ferrochromium and ferrochromium-silicon), and chromium metal. The use of chromite foundry sand post-dated NDS legislation. Since the dissolution of the Soviet Union in 1991, the perceived threat has diminished. As a result, the DLA, by act of Congress, eliminated chromium materials in the NDS and the inventory has been for sale. Figure 23 shows historical NDS chromium material inventories. The last of the ferrochromium-silicon stocks were shipped in 2002 and the last of the metallurgical grade chromite stocks in 2003. The graphs show the National Defense Stockpile conversion program (1984 to 1994; during which chromite was converted to high-carbon ferrochromium and low-carbon ferrochromium was converted to chromium metal), dissolution of the Soviet Union (1991), and the NDS disposal enabling legislation (1993).

Inventories of ferrochromium-silicon were exhausted in 2002; metallurgical grade chromite, in 2003. Continued sales at current rates suggest that NDS inventories will be depleted as follows: chemical-grade chromite by 2006, refractory-grade chromite by 2006, high-carbon ferrochromium by 2011, low-carbon ferrochromium by 2015, and chromium metal by 2020.

Health Factors

Chromium is both an essential nutrient and a toxic substance depending on molecular form (called *speciation*) and exposure (mode, concentration, and duration). Chromium is chemically characterized by its valence state. Common valence states of chromium are chromium 0, chromium 3 (also denoted III, +3, or trivalent), and chromium 6 (also denoted VI, +6, or hexavalent). Chromium 0 is found in metals; chromium (III), in naturally occurring organic and inorganic compounds; and chromium (VI), in industrial chromium chemicals.

Chromium is an essential human nutrient in trace amounts. The National Research Council (NRC 1989) recommended a daily nutritional intake of 50 to 200 µg Cr. Chromium is a cofactor for insulin, a hormone involved in carbohydrate and fat metabolism. A cofactor is a molecule with which certain enzymes must combine in order to be functionally active.

Anderson (1997, 1999) studied the safety of chromium as a nutrient supplement by feeding chromium chloride and chromium picolinate to rats. Data demonstrated a lack of trivalent chromium toxicity at levels several thousand times above that which is estimated to be safe and adequate for daily dietary intake for humans. Animals consuming the picolinate-supplemented diets were found to contain concentrations of chromium several-fold higher in their livers and kidneys than those fed the chromium chloride.

Chromium is a micronutrient that improves the efficiency of insulin in individuals with impaired glucose tolerance. The Institute of Medicine (IOM) reported on the dietary reference intake (DRI) values for chromium based on the diets of healthy Americans and Canadians (IOM 2001). DRI values comprise recommended daily allowance (RDA), a adequate intake (AI), tolerable upper intake level (UL), and estimated average requirement. Life stage and gender affect DRI. IOM found that there were inadequate data to set an RDA; they set an AI, however, based on the

average unit chromium content of balanced diets and balanced diet intakes as reported by the Third National Health and Nutrition Examination Survey, 1988–1994. Data for chromium are not sufficient to develop a UL, suggesting the need for caution in consuming amounts greater than recommended in intakes. Chromium chemical speciation and the route of exposure are important factors in chromium toxicity. Inhaled, hexavalent chromium is carcinogenic. Chromium in food appears universally as trivalent chromium and is nontoxic (Institute of Medicine 2001).

The dietary chemical form of chromium is trivalent. Hexavalent chromium compounds generally are recognized as toxic and carcinogenic. Chronic occupational exposure to hexavalent chromium has been associated with an increased incidence of bronchial cancer. The toxic status of trivalent chromium compounds is not clear; trivalent chromium compounds are less toxic, however, than hexavalent chromium compounds. Chemical compounds containing chromium in lower valence states (i.e., divalent or less) generally are recognized as benign.

The U.S. Department of Health and Human Services (HHS) prepares toxicological profiles for health professionals. HHS reported toxicological and health effect information for chromium (Syracuse Research Corp. 2000).

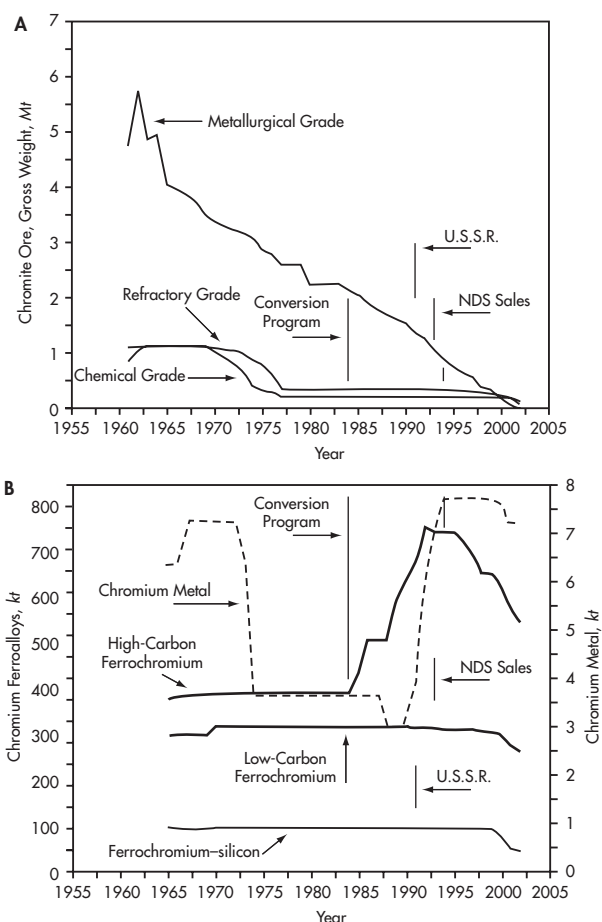

Cross and colleagues (1997) critically reviewed hexavalent chromium exposure limit data in preparation for European Union regulation of hexavalent chromium. They found that hexavalent chromium compounds were potent skin sensitizers in humans and that they caused respiratory sensitization. They reported that speciation is important and relate health effect with solubility in water. Some hexavalent chromium compounds were reported as carcinogenic based on workplace exposure. They found human health effects of hexavalent chromium compounds included carcinogenicity (lung cancer), sensitization, renal toxicity, and irritancy and corrosivity of the skin, respiratory tract, and gastrointestinal tract. They recommended consideration of a time-weighted-average exposure limit in the range of 25 to 10 $\mu\text{g}/\text{m}^3$ to protect the health of workers exposed to hexavalent chromium compounds. Guertin, Jacobs, and Avakian (2005) evaluated the chromium (VI) factors (including persistence in groundwater, taste-and-odor thresholds, health risks, transport and fate, current laboratory analytical methods and detection limits, and regulatory issues) related to water remediation and public policy.

The ICDA (2004a) published industry guidelines on health, safety, and the environment. Guidelines take account of extensive international changes and developments in legislation and regulation of chromium materials that are intended to help companies implement appropriate workplace practices and procedures for environmental protection (Gericke 1998).

Fairhurst and Minty (1998) reviewed the toxicity of chromium and inorganic chromium compounds; included were chromium compounds in valence states 0, +2, +3, +4, and +6. With the exception of chromyl chloride, a volatile liquid, they reported that these compounds were solid at room temperature and that they had a wide range of solubility in water. Solubility and valence state were found to play a role in the behavior of chromium in biological tissue.

Aw (2002) found that the effects of chromium compounds on human health depend on its chemical species. He reported that the health risk posed by hexavalent chromium compounds is established, whereas that of other classes of chromium compounds is uncertain.

Huvinen (2002) described occupational exposure to chromium and its long-term health effects in stainless steel production. Workers in chromite ore mining and ferrochromium and stainless steel production environments were studied. Observed health

Courtesy of Defense National Stockpile Center and USGS.

Figure 23. NDS year-end inventory of chromium-containing materials: (A) various grades of chromite and (B) chromium ferroalloys and metal

effects were minimal for production workers exposed to chromium. Huvinen concluded that it is technically and economically possible to achieve low exposure levels in the stainless steel production chain with no adverse health effects.

Aitio (2001) described the carcinogenic risk of chromic acid mist in electroplating, an area where information has recently been improved. He found insufficient information to quantify the risk; the available information, however, indicates a significant increase of lung cancer risk resulting from inhalation of chromic acid mist. He recommended a range of modifications in chromium plating processing to mitigate the risk to health.

Environmental Regulations

NIOSH (National Institute for Occupational Safety and Health, a part of the U.S. Department of Health and Human Services, Centers for Disease Control and Prevention) is responsible for recommending occupational health and safety standards. OSHA (Occupational Safety and Health Administration, a part of the U.S. Department of Labor) is responsible for promulgation and enforcement of health and safety standards in the workplace.

Environmental concerns have resulted in a wide variety of studies to determine the following about chromium: natural background levels, sources of environmental emissions, movement in the

environment, interaction with plants and animals, effects on plants and animals, measurement methods, and recovery technology. Merian (1991) gave a broad review of many environmental factors and the role of chromium, among other metals, in the environment.

The EPA extended Toxic Release Inventory reporting requirements to seven industry groups that included metal mining, coal mining, electric utilities, and commercial hazardous waste treatment facilities under authority of the Emergency Planning and Community Right-to-Know Act of 1986. These industries started reporting in calendar year 1998 (EPA 1997).

Effluents

Chromium in water effluents must be managed. Solubility of trivalent chromium compounds in neutral pH water usually results in a chromium concentration of <0.1 ppm as required for drinking water. Thus, when water is pH neutralized, filtration can remove chromium. If hexavalent chromium compounds are present, chromium must first be reduced to its trivalent state.

The EPA announced proposed national effluent limitation guidelines and pretreatment standards for wastewater discharges from stand-alone landfills. The EPA maximum recommended concentration of trivalent chromium compounds in freshwater is 570 mg/L, and a continuous concentration of 74 mg/L. The EPA maximum recommended concentration of hexavalent chromium compounds in freshwater is 16 µg/L, and a continuous concentration of 11 mg/L (EPA 1998a, 1998c). The EPA also required community water systems to prepare annual water-quality reports and to provide them to their customers. Reports must contain information about chromium, a regulated contaminant (EPA 1998b).

Emissions

The U.S. Congress enacted the Clean Air Act Amendments of 1990 (Public Law 101-549), completely revising the Air Toxics Program. Congress identified 189 hazardous air pollutants to regulate. Chromium compounds—defined as any chemical substances that contain chromium as part of their structure—were included among those hazardous air pollutants. Under the revised Air Toxics Program, Congress instructed the EPA to regulate hazardous air pollutants by regulating the source of those pollutants. Congress required the EPA to identify pollution sources by November 1991, then to set emission standards for those sources. The EPA eliminated the use of chromium chemicals in comfort cooling towers, one source of chromium emissions. The agency also banned the use of chromium chemicals for corrosion inhibition in industrial process water cooling towers in 1994. It was reported that 90% of industrial cooling tower operators had eliminated the use of chromium chemicals in anticipation of such an EPA ban; the remaining 800 operations were given 18 months within which to comply with the new ruling (EPA 1994).

The EPA, as required under Section 112(c) of the Clean Air Act identified major sources and areas of sources of hazardous air pollutants. The EPA identified chromium electroplaters and anodizers as an area source of hazardous air pollutants that warrant regulation under Section 112 of the Clean Air Act and described the adverse impact of that source. The chromium electroplating industry includes hard chromium platers (usually a thick chromium coating on steel for wear resistance in hydraulic cylinders, zinc diecastings, plastic molds, and marine hardware); decorative chromium platers (usually over a nickel layer on aluminum, brass, plastic, or steel for wear and tarnish resistance for auto trim, tools, bicycles, and plumbing fixtures); and surface-treatment electroplaters or anodizers (usually a chromic acid process to produce a corrosion-resistant oxide surface on aluminum used for aircraft parts and

architectural structures subject to high stress and corrosive conditions). The EPA estimated that 1,540 hard chromium electroplaters, 2,800 decorative electroplaters, and 680 chromic acid anodizers nationwide were affected. They further estimated that electroplaters collectively emit 175 t of chromium per year, most of which is hexavalent and thus carcinogenic in humans. According to the EPA, the resulting U.S. nationwide population risk was an additional 110 cases of cancer per year from chromium electroplating emissions. The resulting individual risk in the proximity of particular facilities ranged from less than 2 chances per 100,000 for small chromic acid anodizing operations to 5 chances per 1,000 for large hard plating operations. OSHA currently promulgates regulations affecting worker exposure at chromium electroplater and chromic acid anodizer operations (EPA 1992).

Solid Waste

The EPA regulates solid waste generated by the chemical industry in the production of sodium chromate and dichromate. Chromium-containing treated residues from roasting or leaching of chrome ore are regulated under Subtitle D of the Resource Conservation and Recovery Act (RCRA). The EPA found no significant danger associated with treated residue from roasting or leaching of chrome ore based on waste characteristics, management practices, and damage case investigations.

The EPA determined that chromium-containing wastes are toxic and established that if a representative waste sample contains chromium concentrations of 5.0 mg/L (total chromium), the waste is hazardous. They also promulgated treatment standards for chromium-containing refractory brick wastes based on chemical stabilization, a process that keeps a compound, mixture, or solution from changing its form or chemical nature. In addition, the EPA determined that some chromium-containing refractory brick wastes can be recycled as feedstock in the manufacture of refractory bricks or metal alloys, and recognized that there is insufficient capacity to process inorganic solid debris (i.e., treatable material >9.5 mm in size that requires cutting or mechanical crushing and grinding) prior to chemical stabilization. As a result, chromite-containing refractory bricks were granted a 2-year capacity variance (i.e., a variance until May 1992) (EPA 1990).

The EPA regulated solid waste disposal of wood treatment waste by setting treatment standards and excluded printed circuit boards and scrap metal from RCRA regulation (EPA 1997).

The EPA proposed to exempt chromite ore mined in the Transvaal Region of South Africa and the unreacted ore component of the chromite-processing residue from this region from reporting requirements under Section 313 of the Emergency Planning and Community Right-to-Know Act of 1986 (EPCRA) (EPA 1999). EPA criteria to add or delete are in Section 313(d) of EPCRA. To be added, a chemical must meet one of the criteria; to be deleted, a chemical must be shown to meet none of the criteria. Petition to delete a chromium chemical was denied on two previous occasions—a 1990 petition to delist chromium antimony titanium buff rutilite and a 1991 petition to delist chromium (III) oxide. In 2001, the EPA granted the request to delete both chromite ore mined in the Transvaal Region of South Africa and the unreacted ore component of chromite processing residue from reporting requirements under Section 313 of EPCRA (EPA 2001).

Safety Regulations

The U.S. Department of Labor regulates chromium in the workplace under OSHA, which reviewed health, risk, and feasibility evidence for chromium metal, chromic acid and chromates, and chromyl chloride. Table 8 summarizes OSHA permissible exposure limits

(PELs). OSHA announced plans to go forward with proposed rule-making on occupational exposure to hexavalent chromium based on a request in 1993 by the Oil, Chemical and Atomic Workers Union and Public Citizen Health Research Group petition to lower the exposure limit (U.S. Department of Labor 2002). The current OSHA PEL for chromic acid and chromates is reported in Table 8 (29 CFR 1910.1000). This table specifies a ceiling limit of $100 \mu\text{g}/\text{m}^3$ of air for all forms of hexavalent chromium, measured as chromium (VI) and reported as CrO_3 . The entry has been unchanged since published in 1971. The OSHA interpretation is that the PEL for chromium (VI) in industry is a ceiling value of $100 \mu\text{g}/\text{m}^3$ of air, measured as chromium (VI) and reported as CrO_3 , as promulgated; in the construction industry, however, the PEL is measured in micrograms per cubic meter as an 8-hr, time-weighted average.

The Health Council of the Netherlands recommended changes to the Netherlands' exposure limits to chromium compounds (see Table 8) based on the health effects of occupational exposure to inhalable toxic substances in the air. For water insoluble chromium (III) compounds, chromium (II) compounds, and chromium metal dusts, they made no recommendation. For water-soluble chromium (III) compounds, they recommended changing the exposure limit from 0.5 to $0.06 \text{ mg}/\text{m}^3$, 8-hr time-weighted average. For chromium (VI) compounds, they recommended an exposure limit of $0.05 \text{ mg}/\text{m}^3$, 8-hr time-weighted average. As part of their review, the council reported occupational exposure limits from Germany, Sweden, and the United Kingdom.

The California Office of Environmental Health Assessment (1994) reported noncancer chronic reference exposure levels to hexavalent chromium. It reported an inhalation reference exposure level of $0.002 \mu\text{g}/\text{m}^3$ for chromic acid and $0.2 \mu\text{g}/\text{m}^3$ for other soluble hexavalent chromium compounds. The same assessment found an oral reference exposure level of $0.02 \text{ mg}/\text{kg}/\text{day}$ for other soluble hexavalent chromium compounds.

FUTURE TRENDS

World chromite production has been rising since 1900, when chemical and refractory use dominated world chromite use. Although the chemical and refractory industries continue to account for a portion of chromite consumption, the metallurgical industry is the dominant user today. The major use for chromite is the manufacture of ferrochromium, which is used as the source of chromium in steel-making. Stainless steel manufacture accounts for most ferrochromium use. Since the discovery and development of stainless steel in the early 1900s, world stainless-steel production has grown both in magnitude and in its share of world steel production. The processes applied to chromite (electric-arc furnace smelting in the metallurgical industry and kiln roasting in the chemical industry) are basically unchanged; many improvements have been made, however, to these processes, increasing productivity, production efficiency, and chromium recovery while reducing costs and emissions. The dissolution of the Soviet Union in 1991 brought previously isolated chromium industries into the global economic system. The effects of that change are still occurring.

Chromite, chromium chemical and metal, ferrochromium, stainless steel, and chromite refractory producers make up the world chromium industry. As ferrochromium production capacity was rationalized in historically producing countries (which traditionally have been stainless steel-producing countries), new furnaces or plants were constructed in chromite ore-producing areas.

Chromite ore production is moving from independent producers to vertically integrated producers; chromite ore mines now tend to be owned and operated by ferrochromium or chromium chemical producers. Associated with this trend is the movement of ferrochromium production capacity from stainless steel-producing countries to chromite-ore-producing countries.

Table 8. PELs for chromium compounds

Material	PEL
United States	
Chromic acid and chromates	$0.1 \text{ mg CrO}_3/\text{m}^3$, ceiling
Chromium metal and insoluble salts	$1.0 \text{ mg Cr}/\text{m}^3$, 8-hr time-weighted average
Soluble chromic and chromous salts	$0.5 \text{ mg Cr}/\text{m}^3$, 8-hr time-weighted average
The Netherlands	
Chromium metal dust	$0.5 \text{ mg}/\text{m}^3$, 8-hr time-weighted average
Soluble chromium (VI) compounds	$0.5 \text{ mg}/\text{m}^3$, 8-hr time-weighted average
	$0.1 \text{ mg}/\text{m}^3$, 15-min time-weighted average
Calcium-, strontium-, and zinc chromate	$0.01 \text{ mg}/\text{m}^3$, 15-min time-weighted average
Lead and barium chromate	$0.025 \text{ mg}/\text{m}^3$, 15-min time-weighted average
Combined chromium exposure	$0.01 \text{ mg}/\text{m}^3$, 15-min time-weighted average

mium production capacity from stainless steel-producing countries to chromite-ore-producing countries.

Both electrical power capacity and production capacity of submerged-arc electric furnaces used in the production of ferrochromium have been increasing, whereas the unit consumption of electrical power and emissions has been declining. Retrofitting at major producer plants has improved production processes such as agglomeration of chromite ore to prevent it from blowing out of the furnace during smelting; preheating of furnace feedstock to reduce electrical energy consumption; and closed furnace technology to reduce emissions. These improvements also are being incorporated into newly constructed plants. The first industrial ferrochromium furnaces were rated in low kilovolt-amperes, whereas furnaces built recently have electrical capacities in the tens of megavolt-amperes. The capacities of ferrochromium plants, as well as the chromite mines that supply them, has been increasing. In effect, chromite is becoming more like a bulk commodity. As chromite and ferrochromium production has grown, so too have investments and sales, while production has been concentrated in only a few companies. Although the amount of production has increased, the number of producers has decreased. As the industry grows, mines and plants get larger and the capital cost barrier to market entry rises. As a result, new entrants into the market tend to be absorbed by established producers.

The introduction of post-melting refining in the steel industry after 1960 shifted ferrochromium production from low-carbon to high-carbon grades. Years of ferrochromium production have resulted in large slag stockpiles. Processes that recover ferrochromium from slag have recently improved in recovery efficiency. These processes have been or are being installed now at plant sites. In South Africa, the leading chromite- and ferrochromium-producing country, two trends are emerging: ferrochromium plants are being developed in the western belt of the Bushveld Complex and ferrochromium production processes have begun to use chromite by-product from platinum operations.

In the United States, chromite use has declined dramatically; the demand for chromium, however, is well established and is increasing, especially for chromium ferroalloys and metal imported for metallurgical use, mostly to make stainless steel. Chromite use

in producing chromium ferroalloys and for refractories has ended and chemical industry demand has decreased substantially. U.S. industry has replaced domestic chromium ferroalloys and refractory materials with imports, and demand for chromium chemicals has declined.

In the United States, several trends are developing simultaneously in chromium industries. Ferrochromium production from chromite declined to zero in the United States in 1998. Chromite use for chemical production grew slowly, with industry eliminating excess, uneconomic capacity, and concentrating production and growth in surviving plants until 2002, when production dropped dramatically. This left one chromite-consuming chemical plant in the United States. Chromite use for shaped and unshaped refractory materials declined to zero in 2003; foundry use, however, has been growing slowly.

Environmental regulations are affecting chromite consumption, primarily in the chemical and refractory industries. Regulations limiting worker exposure and limiting chromium in emissions, effluents, and solid wastes continue to increase operating costs and, for new operations, capital costs.

Chromium-related businesses are international in nature. Chromium-containing materials are mined and processed in various countries, but chromium-containing industrial and consumer products also are distributed and used throughout the world. Diverse regulations on product manufacturing, labeling, and shipping are concerns for the chromium industry. It will be affected most by the regulatory requirements of its most important markets. Similarly, health and safety regulations adopted by countries where chromium-containing materials are processed and used will continue to affect the industry.

Economic growth in China resulted in chromium industry growth. Industrial growth in China required the construction of infrastructure and industrial plants and equipment, processes that are steel intensive. China mines little chromite ore; however, it manufactures ferrochromium from imported chromite. Since 2003, China expanded its stainless steel industry by constructing modern, large-capacity stainless steel production plants, turning itself into a major chromite ore and ferrochromium consumer. Continued growth in China and a similar economic transition in India were anticipated; however, the duration of growth in China and the economic path that India will follow remain unclear.

ACKNOWLEDGMENTS

The contribution of Harry Mikami by his authorship of interesting and informative chromite chapters in earlier editions of *Industrial Minerals and Rocks* is acknowledged. Much of the information provided in those chapters remains useful. The authors also wish to thank the ICDA for providing information about the chromium industry. Industry sources were very helpful and generous in providing information about their respective industries and products.

An Overview

Colin C. Harvey and Haydn H. Murray

INTRODUCTION

The term *clay* is somewhat ambiguous unless specifically defined, because it is used in three ways:

- As a diverse group of fine-grained minerals
- As a rock term
- As a particle size term

As a rock term, clay is difficult to define because of the wide variety of materials that comprise it; therefore, the definition must be general. Grim (1962) defined clay as a fine-grained, natural, earthy, argillaceous material. The particle size of clays is very fine and is generally considered to be about 2 μm or less by most clay scientists. These minerals are hydrous silicates composed mainly of silica, alumina, and water. Several of these minerals also contain appreciable quantities of magnesium, iron, alkalis, and alkaline earths. Many definitions state that a clay is plastic when wet. Most clay materials do have this property, but some clays are not plastic, such as halloysite and flint clay.

As a particle size term, clay is used for the category that includes the smallest particles. The maximum size particles in the clay size grade are defined differently on various grade scales. Soil investigators and mineralogists generally use 2 μm as the maximum size, whereas the widely used scale by engineers (Wentworth 1922) defines clay as material finer than approximately 4 μm .

Some authorities find it convenient to use the term clay for any fine-grained, natural, earthy, argillaceous material (Grim 1968). When used in this way, the term includes clay, shale, argillite, and some fine soils.

Even though no standard definition of the term clay is accepted by geologists, agronomists, engineers, and others, the term is generally well understood by those who use it. Clay is an abundant natural raw material, and it has an amazing variety of uses and properties, which are discussed in the following chapters.

Clay Types and the Clay Chapters

The following seven chapters, written by experts on clay mineralogy, categorize the clay minerals on the basis of their composition:

- Ball clays
- Bentonite
- Common clays and shale
- Fuller's earth
- Kaolin

- Palygorskite and sepiolite (hormites)
- Refractory clays

There is some overlap between fuller's earth, bentonite, and hormites because they all have similar properties for some applications. Therefore, both the bentonite and palygorskite-sepiolite chapters discuss fuller's earth. *Fuller's earth* is a term based on use, and both bentonites and hormites may be sold as fuller's earth. The overlap is particularly evident where both bentonite and nonbentonite fuller's earth are used for the same purposes or products, such as in drilling mud, for bleaching or clarifying fats and oils, and as carriers for insecticides and fertilizers. Kaolin, ball clay, halloysite, and refractory clays are sometimes grouped together because they consist mainly of minerals of the kaolin group. Common clays have no unique mineral composition and may be composed of any mixture of the clay types and other fine-grained materials, including shale, sometimes referred to as miscellaneous clay.

WORLD PRODUCTION STATISTICS

Unfortunately no comprehensive world production statistics are available for the clay minerals. The U.S. Geological Survey (USGS; Virta 2003) publishes an annual review of statistical data but, unfortunately, numerous countries, including India and China, are not always included. Virta (personal communication) estimates that the recorded world production figure for kaolin reported by individual countries may also include the actual mined tonnage figures and does not take into account the losses incurred during processing. Although Virta (2003) quotes a world tonnage of 43 Mtpy of kaolin, he believes that the tonnage actually sold (raw plus processed) is closer to 26 Mtpy. His statistics, however, do not include China, India, and many former eastern bloc countries. Besides this estimate of world production of about 26 Mtpy of kaolin, other clay types include 10.3 Mtpy bentonite, 3.9 Mtpy of fuller's earth, and 13 Mtpy of ball clay, whereas hormite (palygorskite-sepiolite) production is estimated to be about 3 Mtpy.

The amount of common clays used worldwide is difficult to estimate since there are no comprehensive statistics. It is likely, however, to exceed many hundreds of million metric tons/year. Statistics for refractory clays also are not well documented. Their world production, however, exceeds 10 Mtpy and may indeed exceed 20 Mtpy. There are also a few unique deposits of high-purity clays such as halloysite (used in high-quality porcelain and catalysis) and hectorite (used in cosmetics and pharmaceuticals).

Table 1. World production estimates

Clay Type	2002 World Production, Mt	Reference
Common	Hundreds	Estimate only
Refractory	Possibly more than 20	Estimate only
Kaolin	43 mined 26 sold	Virta 2003
Bentonite	10.3 V	irta 2003
Fuller's earth	Uncertain—possibly 10

Talcum, pyrophyllite	Plastics, rubber, paper	Filler
	Cosmetics, pharmaceuticals	Powders, pastes, ointments, lotions
	Refractories	Refractories
Palygorskite, sepiolite	Pesticides	Carrier for insecticides and herbicides
	Chemicals	Catalyst carrier, filter material, anticaking agent
	Cosmetics, plastics	Filler

that have unique properties leading to their classification as high-quality additives rather than bulk industrial minerals.

In addition, some nonclay minerals—finely ground to have similar properties to some industrial clays—are also frequently included in industrial clay surveys. These minerals include vermiculite, mica, talc, and pyrophyllite. The individual chapters present production statistics of the individual clays. Table 1 summarizes the estimated overall world production of clay minerals by both USGS sources and others.

CLAY USAGE

Clays and clay minerals are very important industrial minerals. They are used in many process industries, in agricultural applications, in engineering and construction, in environmental remediation, and in many other diverse applications (Grim 1962; Grim 1968; van Olphen 1977; Patterson and Murray 1983; Jepson 1984; Odom 1984; Murray 1986, 1999, 2000, 2003; Darley and Gray, 1991; Bundy 1993; Galan 1996; Harvey and Murray 1997; Ravichandran and Sivasankar 1997; and Philippakopoulou, Simonetis, and Economides 2003).

Table 3. Uses of clay minerals based on their rheological properties

Clay Family	Industry	Uses
Common clays	Ceramics	Tiles, bricks, earthenware, stoneware, sewer pipes, sanitary ware, refractory bricks
Kaolins	Paper	Coating
	Ceramics	Porcelain, bone china, vitreous sanitary ware, earthenware
Bentonites	See Table 4	
Palygorskite, sepiolite	Paints, chemicals, and mineral oils	Thickening and thixotropic additive, dispersing and antisetling agent, drilling fluids

Clay usage falls into two broad classes:

- Clays are used because their inertness and stability provide specific properties (such as unique rheology) to an industrial use. This leads to large variety of industrial applications.
- Clays are used because of their reactivity, which promotes or catalyzes specific reactions.

Tables 2, 3, 4, and 5 give a brief summary of uses; the individual chapters give a more detailed breakdown.

CLAY MINERAL STRUCTURES

All the clay minerals are basically hydrated aluminum silicates. There are, however, significant structural and chemical differences, which may include substitution of many cations that affect the neutrality or stability of the clay mineral. For example, iron or magnesium may substitute for aluminum; aluminum may substitute for silicon; and in some clay minerals, alkalis and alkaline earth elements are present as essential constituents. The structure of all the clay minerals consists of sheets of silicon tetrahedra and aluminum octahedra arranged in differing patterns for each individual clay mineral.

The physical properties of a particular clay mineral depend on the structure and composition (Murray 2000). Because of their extremely fine particle size, clay minerals were very difficult to identify until the advent of x-ray diffraction in the 1920s. Today, sophisticated analytical equipment is available to fully identify and characterize the clay minerals. The more important analytical methods that are used include x-ray diffraction, x-ray fluorescence, electron microscopy, infrared spectroscopy, and differential thermal analysis.

PHYSICAL AND CHEMICAL PROPERTIES

The important physical and chemical characteristics that relate to the applications of clay minerals are particle size, shape, and distribution; surface chemistry, area, and charge; pH; high and low shear viscosity; filter cake permeability; color and brightness; opacity; plasticity; green, dry, and fired strength; absorption and adsorption; fired color; electrical and heat conductivity; abrasion; cation and anion exchange capacity; refractoriness; dispersability; and thixotropy. The clay chapters each delineate and discuss these and other special properties. In most industrial applications, the clay materials are functional rather than just inert components in the system in which they are used. The common clays are the largest to manage usage in numerous engineering applications, including road construction, fill, and dam construction, and in waste containment. The mineralogy and particle size distribution in the common clays determine their engineering properties. They contain mixtures of different clay minerals such as illite/smectite minerals, kaolinites,

Table 4. Uses of bentonites based on their rheological properties

Industry	Uses	Activation*
Agriculture, horticulture	Soil improvement	r, s
Building	Supporting dispersions for cut-off diaphragm wall construction, shield tunneling, subsoil sealing, antifriction agents for pipejacking and shaft sinking	r, s
	Additions to concrete and mortar	r, s
Ceramics	Plasticizing of organic masses, improvement of strength, fluxing agents	r, a
Foundries	Binding agents for molding and core sands	r, s
	Binding agents for anhydrous casting sands	o
	Thickening of blackwashes	o
Mineral oil	Drilling fluids	r, a, o
	Thickening of greases	o
Paints, varnishes	Thickening, thixotrope, stabilizing, antisetling agents	s, o
	Coating materials, sealing cement, additives for waxes and adhesives	s, o
Cosmetics, pharmaceuticals	Bases of creams, ointments, and cosmetics	r, a, s
	Stabilization of emulsions	r, o

	Tar and asphalt coatings, additives for bitumen	

* Bentonites are used as raw materials or in activated form: r = raw bentonite, a = acid-activated bentonite, s = soda-activated bentonite, o = organo-bentonite.

smectites, micas, and accessory minerals. A second class is termed *industrial kaolins*, which are recognized by their relatively high contents of kaolinite (kaolins) or sometimes a small proportion of high-quality kaolin minerals. Ball clays have very fine particle size and are composed predominantly of kaolin. A fourth class is clay that has a high montmorillonite (smectite) content (bentonites). A fifth class is the palygorskite and sepiolite clays (hormites), which have many similarities to bentonites and are used specifically for their surface properties and reactivity.

CLAY MINERAL SOCIETIES AND PUBLICATIONS

Several scientific societies and groups are devoted to the science and applications of clays. The major societies and groups that are currently active in clay science are as follows:

- The Clay Minerals Society in the United States
- The European Clay Group, which includes most of the European countries
- The Clay Science Society of Japan
- The Association Internationale pour l'Etude des Argiles (AIPEA)

Many of the individual clay groups in European countries hold meetings periodically. The Clay Minerals Society hosts an annual conference in the United States and publishes the journal *Clays and Clay Minerals*, plus special publications and workshop proceedings. The European Clay Group holds a Euroclay Conference every 2 years and publishes the journal *Clay Minerals*. The Clay Science Society of Japan sponsors an annual conference and publishes the journal *Clay Science*. AIPEA sponsors the International Clay Conference every 4 years and publishes the proceedings. The journal *Applied Clay Science* is published by Elsevier. Other organizations

Table 5. Uses of clay minerals based on their adsorption properties and reactivity

Clay Family	Industry	Uses
Kaolin	Fiberglass	Source of alumina
	Petrochemicals	Catalyst support
	Chemicals	Zeolite synthesis
Bentonite	Building	Additive in cement
	Agriculture, horticulture	Soil improvement, composting
		Adsorption of mycotoxins
	Chemicals	Sulfur production: refining, decoloration, bitumen extraction
		Catalysts
		Carriers for pesticides
		Dehydrating agents
		Adsorbents for radioactive materials
	Cleaning	Regeneration of organic fluids for dry cleaning
		Polishes and dressings
Palygorskite, sepiolite	Environmental technology	Additives for washing and cleaning agents and soap production
		Forest and water conservation: fire extinguishing powders, binding agents for oil on water
		Animal husbandry, manure treatment, cat litter
		Water and wastewater purification
		Sewage sludge pelletizing
	Food	Barriers
		Refining, decoloration, and stabilization of vegetable and animal oils and fats
		Fining of wine, must, and juices, beer stabilization, purification of saccharine juice and syrup
		Refining, decoloration, purification, and stabilization of mineral oils, fats, waxes, and paraffins
		Pigment and color developer for carbonless copying paper
Palygorskite, sepiolite	Cosmetics, pharmaceuticals	Adsorption of impurities in circulation water
		De-inking in wastepaper recycling
		Powders, tablets, drug carrier, odor control, liquid absorption
		Adsorbent, carrier, bleaching, decoloration, anticaking agent
		Cigarette filters (sepiolite), cat litter

and publications that feature articles on clays are the American Ceramic Society (annual meetings and monthly bulletin); SME (annual meetings, preprints, *Mining Engineering* magazine, books, and transactions); and *Industrial Minerals* magazine.

The scientific and technological publications pertaining to clays are too numerous to cover in this chapter. Therefore, the rest of this chapter summarizes the subject matter and, where possible, indicates by bibliographic reference where more detailed information is available. For example, Bicker (1970) is a bulletin containing only summary information on the economic geology of bentonite in Mississippi, but it contains references to virtually all published reports on bentonite in that state.

Major textbooks and reference volumes on various aspects of clay mineralogy and the industrial uses for clay published in the last 5 decades include Mackenzie (1957), Grim (1962, 1968), Zvyagin (1967), Beutelspacher and Van Der Mar el (1968), Gillott (1968), Clews (1969), Malkovský and Vachti (1969a, 1969b, 1969c), Carroll (1970), Gard (1971), Weaver and Beck (1971), Grimshaw (1972), Weaver and Pollard (1973), van Olphen (1977), Theng (1979), Brindley and Brown (1980), Velde (1985), Robertson (1986), Newman (1987), Bailey (1988), Chamley (1989), Murray, Bundy, and Harvey (1993), Moore and Reynolds (1997), Pinnavaia and Beall (2000), Worden and Morad (2003), and Kloppe (2005). Many other excellent books on clays could be mentioned. Various provincial, state, and federal geological surveys, mining bureaus, and other international agencies have also published much information on the geology, technology, and uses of clay.

Within the United States several industrial groups with similar industrial processes and markets have formed institutes or associations to share information, standardize specifications and test procedures, and lobby government or trade organizations for support. They include the following:

- The Sorptive Minerals Institute, formed mainly to represent the producers of absorbent granules and other fuller's earth products
- The Bentonite Producers Association, organized to represent the interests of the producers of bentonite
- The U.S. Clay Producers Traffic Association, incorporated in 1953 in New Jersey
- The China Clay Producers Association

In addition to these organizations dealing specifically with clays, the clay industry and other mining industries formed mining associations in many states, including Georgia and Texas in 1972, to protect their interests against restrictive state and federal legislation.

OCCURRENCE OF CLAY MINERALS

Clay resources may be formed from weathering processes, diagenesis, metamorphism, or hydrothermal processes. The nature of the formation process significantly affects the crystallinity and purity of the clay and its associated minerals. Resources that are still in situ after the formation processes are termed *primary clay resources* whereas, if subsequent erosion, sorting, and sedimentation occur, thereby concentrating the finer clay minerals, the resources are termed *secondary clay resources*. The origin of all clay types is discussed under the individual clay chapters. Pure clays do not usually occur in nature.

TECHNOLOGIES FOR CLAY PROCESSING

The processing technologies for clays are diverse. Many clays are used as mined, some are dry processed using air classification, whereas others are wet processed, chemically modified, or processed using a variety of complex processing steps. The individual clay chapters discuss these processes.

CATEGORIZATION OF CLAY RESOURCES

With the continued world population growth and movement toward urbanization and industrialization, there is an ongoing and growing need throughout the world to develop resources of industrial clays. During the early to middle part of the 20th century, developments in the industrialized world typically began on a small scale from a low technology base. The initial market focus was on construction materials or relatively low-quality ceramic products. With increas-

ing levels of industrialization, the level of technology and product sophistication increased, with the ultimate objective of achieving high product quality.

Over the past 20 years, the developed world has experienced the following:

- The exhaustion of many natural resources
- Mature low-growth markets
- Increasing environmental constraints
- Higher labor costs
- A general movement against mining in many countries

This has encouraged interest and investment in resources in developing nations. In addition, growth in the gross domestic product (GDP) of many developing nations has provided investment capital for the development of their indigenous clay mineral resources.

On the basis of many industrial clay mineral studies in both developed and developing countries, it has been found that categorizing industrial clays into one of four categories is a useful precursor to undertaking technical and economic evaluations of potential resources. Such categorization also benefits the explorer or developer because it:

- Assists in identifying the most suitable development strategy
- Provides a general estimate of the time required to move from greenfield development to production
- Enables a work program to be broadly defined
- Permits provisional project cost estimates to be made

Categories of Industrial Clays

Clay resources fall in to four categories (Harvey and Murray 1997):

- Category 1 clays are high-quality, high-technology clays requiring major investment for large tonnage production to supply both local and international markets.
- Category 2 clays are unique specialty clays requiring advanced technologies for small tonnage niche markets, locally and internationally.
- Category 3 clays include low-technology, moderate-quality clays that mainly supply local markets.
- Category 4 clays are of variable quality.

Category 4 low-quality clays may justify little or no processing but be suitable for large tonnage local markets. Some Category 4 clays may be of moderate to high quality but for one or more reasons are considered noneconomic. These reasons may include:

- Isolation from markets
- Politically or economically unstable locations
- Unfavorable legislative environment

Examples of Different Categories

Category 1

Three regions (kaolin provinces) currently produce Category 1 kaolin clays:

- The sedimentary kaolins of southeastern Georgia in the United States
- The hydrothermal kaolins of Cornwall in the United Kingdom
- The sedimentary kaolins of the Amazon Basin in Brazil

The limited number of kaolin resources identified in this category confirms the rarity of Category 1 clays currently known worldwide. They are discussed in detail in the Kaolin chapter.

Category 2

There are also very few resources that might be classified as Category 2. These are relatively rare, unique resources of somewhat unusual, but valuable industrial clay minerals. Such deposits are typically of high purity and are found in somewhat unique geological settings. Examples include the halloysite deposits of New Zealand, which are unusually pure deposits of halloysite formed by low-temperature hydrothermal alteration of volcanic ash (Harvey and Murray 1993, Harvey 1996). Halloysite is wet processed and supplied to a unique niche market in high-quality ceramics.

A second example is hectorite, a lithium smectite that also is the product of hydrothermal alteration. In this case, basaltic ash with elevated concentrations of magnesium and lithium was subjected to hydrothermal alteration, forming this lithium smectite (bentonite). It is wet or dry processed and used in a wide variety of industries (coatings, greases, adhesives, and paints) because of its high viscosity, high gel strength, and good temperature stability.

A third example is white bentonite, which is very rare in nature and commands high prices in colloidal applications, detergents, pharmaceuticals, and ceramics. For some specialty markets, these bentonites are wet processed or surface modified to achieve the high quality required for such applications.

Category 3

Category 3 resources are numerous and widespread. Their specifications are typically not rigid, which means that the level of processing is typically only moderate because the market quality requirements and pricing cannot justify high processing costs. All of the known Category 1 resources around the world also contain large tonnages of these clays, which are too impure to meet Category 1 requirements. Examples of large exploited resources of Category 3 clays associated with Category 1 clays are the filler kaolins of Georgia (United States) and of Cornwall (United Kingdom). Other Category 3 resources contain few if any Category 1 component. These include the kaolin resources of Central Europe in the Czech Republic, Ukraine, and Germany; the filler grade kaolins of Indonesia; and the bentonite resources of Wyoming and the southeastern United States.

An example of a Category 3 clay is the Belitung kaolins of Indonesia. During the 1960s and early 1970s these primary kaolins were mined as an adjunct to the associated, highly profitable, tin mining operations. With the radical drop in tin prices during the 1970s and 1980s, more emphasis was placed on the kaolin operations. These clays are currently exploited to supply large ceramic and filler clay markets within Indonesia and they are also exported to Asian countries, including Taiwan, Japan, and South Korea.

Category 4

Category 4 clays exist in all countries of the world and are typically used as mined.

Role of Categorization in Assessing Industrial Clay Resources

In any assessment of an industrial clay resource the explorer or developer has to go through the various stages of resource assessment, raw material testing, and assessment of product quality, market size, and market demand. All these data must then be integrated into a feasibility study that will recommend whether the project should proceed or be abandoned. An early classification of materials into one or more of the four categories can be a useful precursor to establishing development strategies and likely project costs. Such categorization can provide a useful insight into the complexities of such studies because these different categories have different requirements for the work program needed and the time frame to reach the feasibility study.

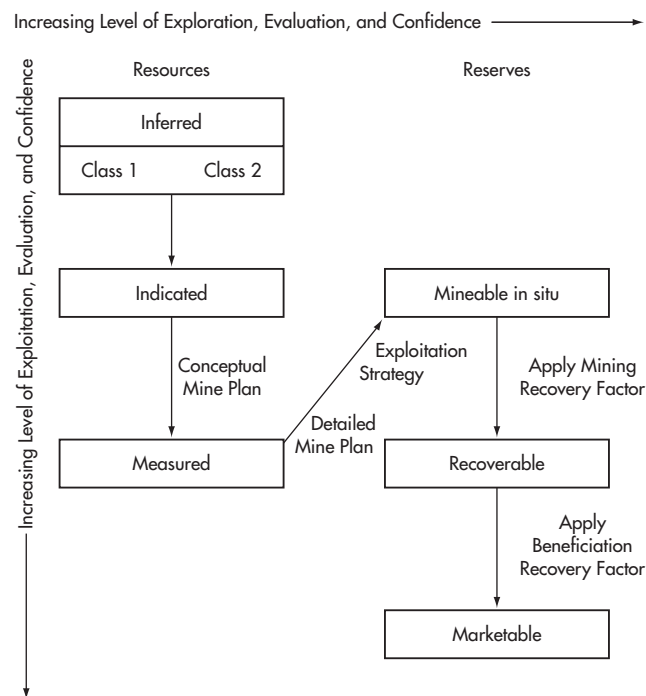

Figure 1. Flow chart showing levels of confidence and assessment of mineral resources and reserves

Relationship between Category and Annual Tonnage

In any mineral processing operation, the term *benefits of scale* is used to indicate that significant economic advantages can be obtained by having larger production volumes and by shipping in larger vessels. Larger tonnage operations operate with fewer labor hours per ton whereas capital costs for larger machines are less than the multiples of their relative production capacities. To compete on world markets, Category 1 producers must consider the benefits of scale. In the kaolin industry in the 1970s, for example, a 100,000 tpy operation was considered a reasonable commercial operation. For the current developments in Brazil, a minimum plant size of 300,000 tpy is being quoted. Category 2 clays have annual tonnage requirements that are governed by market size rather than benefits of scale. Annual production from such processing operations typically falls between 10,000 and 100,000 tpy. The sizes of Category 3 operations are typically governed by factors such as market size or accessible market share.

Relationship between Category and Resource Confidence

Based on the category criteria, the development of a Category 1 resource requires a very high level of confidence in the quality and quantity of the raw material. If a minimum resource life of 20 years is required at 300,000 tpy, then the resource must be of sufficient size to produce 6 Mt of product. For Category 2 and Category 3 industrial clays, the tonnage requirements may be significantly less and resource confidence may also be less.

Figure 1 shows the various levels of resource certainty that are internationally recognized in the classification of industrial mineral resources.

The lowest level of confidence (*Inferred*, in the upper left corner), exists when no drilling or detailed testing has been carried out. The level of confidence moves from *Inferred* to *Indicated* when an initial exploration and testing program has been carried

Figure 2. Flowsheet of project development

out and the boundaries of the resource in three dimensions may be reasonably estimated. Once a systematic exploration, drilling, and testing program has been completed, the level of confidence moves to *Measured*.

This may result in a prefeasibility study when a decision is made to proceed or withdraw from the project. If the project proceeds, then further drilling and testing leads to a mine plan, exploitation strategy, and calculations of *Mineable in situ* tonnages. A recovery figure for mining and processing may then be applied to calculate the *Recoverable* and *Marketable* reserves.

For resources in Categories 1 and 2 it is essential that the knowledge be at the Marketable reserves stage. For Category 3 minerals, the resource certainty may be much less, possibly at the *Inferred* resource level or less.

Relationship between Category and Value

Category 1 kaolin products command the largest tonnage and highest added-value positions in the industry. Frequently, however, it is the Category 2 products that command the highest unit value position, although their tonnages may be relatively small. Category 3 kaolins command an intermediate value between Category 1 and Category 4 kaolins.

Relationship between Category and Preinvestment Capital

Category 1 projects require significant preinvestment or “risk” capital. The level of confidence in the resource and markets has to be very high, requiring a significant level of investment that may well exceed US\$1 million. The payback time for such investments can be at least 5 years because of the time required to move from

reconnaissance to commissioning. The pre-investment capital requirements for Categories 2, 3, and 4 become progressively lower as the category of clay moves lower.

Relationship between Category and Investment Capital

The investment capital requirements for large tonnage, high-complexity Category 1 kaolin projects are quoted to be as high as US\$300 per processed ton (Harvey 1995; Pleeth 1997). For Category 2 kaolins, investment capital costs would depend on the complexity of the process but might range between US\$100 and US\$500 per processed ton. For Category 3 kaolins, the investment level may be less than US\$50 per finished ton.

THE RESOURCE EVALUATION PROCESS

The evaluation moves through a series of progressively more detailed stages as shown in Figure 2.

Translating from Laboratory-Scale Testing to Major Plant Scale

The clay industry has many examples of insufficient scale-up factors being applied to basic laboratory data. This ranges from basic recovery figures to assessments of product quality based on too few laboratory test data. For example, losses during commercial plant operations may be much higher than in small-scale laboratory test equipment. A conservative approach to both laboratory- and pilot-scale test data is essential.

The Level of Applied Technology

Almost anything can be done with a low-grade clay resource if a sufficient number of applied technologies are thrown at it. For example, with commercial kaolin resources, a wide-ranging selection of technologies can be applied. By applying a number of such technologies to a low-grade raw material, it may be possible to upgrade it significantly. When all the various processes are costed into the operation, however, the total expenditures (and process losses) may become prohibitive, effectively constraining development of the resource.

Losses Associated with Applied Processing Steps

For each technology introduced into a process there will be process losses. These may range from 2% to much higher values. If, however, it is generalized that each process step loses 4% of product, then the effects of multistage processing on recoveries may be very significant. Also, such losses will be cumulative.

Time to Move from Commissioning to Full Production

Industries that use industrial minerals are often conservative by nature and do not readily accept new products. For example, the paper industry uses a complex technology, and an industrial clay such as kaolin may be just one component in a complex formulation. Purchasing agents may have to be convinced that the product is compatible with their formulations, and further, that the product quality and supply will be consistent. To reach this stage, it is necessary to convince the company of the quality, consistency, and value of a new product over and above the quality of its existing supplier. In such cases it may be necessary to compete on the basis of higher quality, lower price, better continuity, or better technical support. Even with such strengths, however, the new player in the marketplace still has to deal with buyer conservatism. Therefore, the rate at which a product is accepted may be a combination of advantageous positioning and sheer luck. For some products, it may take years to gain full market acceptance. For example, recent developments of Category 1 kaolin resources in Brazil (Pleeth

Table 6. Timetable of activities and investments

Activity	Category			
	1	2	3	4
Stage I: Reconnaissance				
Geological reconnaissance, property surveys, testing, broad categorization of materials, market surveys and evaluation				
Decision to proceed (months)	12	9	6	3
Stage II: Exploration (prefeasibility)				
Property negotiation, drilling, testing, market surveys, precise material characterizations, process flowsheet development, resource calculations, economic studies and evaluation				
Prefeasibility study and decision to proceed (months)	18–24	9	9	6
Stage III: Delineation and feasibility				
Drilling, testing, market surveys, bulk samples, engineering studies, assessment of products in the marketplace, economic studies and evaluation				
Feasibility study (months)	24	12	9	3
Stage IV: Decision to invest				
Total elapsed time since project initiation (years)	4–5	2.0–2.5	2	1
Design, construction, and commissioning (years)	1–2	1	1	1
Typical overall project time (years)	5–7	3–4	2–3	1

1997) quote time intervals of at least 5 years to move from initial exploration through to commissioning. Table 6 illustrates typical times required.

Reducing Risk during Development

There are several procedures for minimizing risk and reducing the time necessary to develop Category 1 or Category 2 ventures:

- Associate or form a joint venture with established producers in the industry.
- Associate or form a joint venture with major market users of the product.
- Engage specialized consultants for resource evaluation, market surveys, and so forth.
- Develop resources adjacent to proven established resources.

SUMMARY

This overview illustrates the diverse nature of clay minerals and the breadth of their technologies and markets, and demonstrates why they are such important industrial minerals. The seven chapters that follow expand on the individual clay types.

Ball Clays

Jason McCuiston and Ian Wilson

INTRODUCTION

Ball clays are kaolinitic sedimentary clays that are an important component in most ceramic bodies because they confer strength and plasticity. Most ball clays impart a light cream to white fired color in an oxidizing atmosphere. Ball clays have varying proportions of kaolinite, illitic mica, or sericite and fine quartz, with small amounts of organic matter and other minerals such as smectite. They are commercially valued because they increase the workability and strength of ceramic bodies. Contaminant minerals frequently include pyrite, siderite, iron and titanium oxides, gypsum, and dolomite. The quantity, form, and type of contaminant can influence the usefulness, processing route, and ceramic application of the clay. The major differences between the kaolinite in ball clay and in china clay (kaolin) are particle size and the degree of ordering within the crystal structure. Whereas the kaolinite in china clay is moderately

coarse and generally well ordered, kaolinite in ball clay normally has a very fine particle size and is predominantly b-axis disordered.

The term *ball clay* is thought to be derived from the old method of working the clay. The clay was cut into cubes about 9 in. (230 mm) square, each weighing 30–40 lb (13–18 kg); because of the plastic nature of the clay, these rapidly assumed a spherical shape during handling. Clay was sold in this form by the “ball.” Alternatively the name may have derived from a digging implement called a “tubal,” which is still used to mine ball clay in some parts of the world.

Figure 1 shows the locations of some of the major deposits worldwide. In 2003, the production of ball clay was estimated at 15.5 Mt (Table 1), and this should be considered only an estimate because many countries do not distinguish between ball clays and other types of clays. Nine countries—China, Germany, Indonesia,

Table 1. Estimated ball clay production by region/country, 2002–2003

Region/Country	Production, t
North America	
United States	1,120,000
Europe	
Czech Republic	400,000
France	400,000
Germany	3,000,000
Italy	100,000
Poland	50,000
Spain	1,200,000
Turkey	550,000
Ukraine	3,500,000
United Kingdom	1,000,000
Asia and Oceania	
Australia	80,000
China	2,000,000
India	150,000
Indonesia	500,000
Malaysia	600,000
Thailand	300,000
Vietnam	200,000
Others	
Argentina	50,000
Brazil	250,000
Chile	5,000
South Africa	10,000
Total	15,500,000

Malaysia, Spain, Turkey, Ukraine, the United Kingdom, and the United States—account for 83% of the world's production with the largest, Ukraine, at 23% (Figure 2). The most significant development has been the dramatic increase in production from Ukraine mainly for the manufacture of Gres Porcellanato tiles. The clay is characterized by high strength, fine particle size, and particularly low water absorption, which is especially suitable for single firing.

This chapter describes the ball clays of the United States in detail followed by a brief review of some other deposits of the world.

BALL CLAYS OF THE UNITED STATES

Local potters near Paris, Tennessee, in the 1800s were the earliest ball clay miners in the United States after European settlement. In 1894, Isador Mandle began selling clays out of state from Whitlock, in Henry County, Tennessee (Whitlatch 1940). Ball clay mining subsequently spread across Henry, Weakley, and Carroll counties in Tennessee and north into western Kentucky. With the migrations and population growth farther west, ball clay resources were discovered and exploited in California, Maryland, Mississippi, and Texas.

The four major suppliers of ball clay in the United States are H.C. Spinks Clay Company (Franklin Industries); Kentucky–Tennessee Clay Company (Imerys); Old Hickory Clay Company; and Unimin Corporation.

The major markets for ball clay are in the manufacture of sanitary ware, wall tile, and floor tile. Ball clay is also used in the manufacture of acoustic ceiling tile, dinnerware, electrical porcelain,

**Figure 2. Major ball clay producing countries, 2002–2003**

refractories, hobby ceramics, coal tar/asphalt, fiberglass, rubber, and a variety of coating and sealant applications.

Production and Trade

According to U.S. Geological Survey (USGS) statistics, in 2002, approximately 1,120,000 t of ball clay valued at US\$47 million was produced in the United States (Table 2). Tennessee was the largest producer at 59%, followed by Texas, Kentucky, and then Mississippi. Most of this tonnage was produced for ceramic applications (floor and wall tile, 35%; sanitary ware, 22%; pottery and miscellaneous ceramics, 15%). Figure 3 illustrates the distribution to each market.

Processing

Raw ball clay is processed into four different forms: shredded, mechanically dried, air-floated (powdered), and slurry. Shredded ball clay undergoes the least amount of processing. In this process, raw clay is run through a shredder, and the resulting product is no more than 2 in. (5 cm) in diameter with a moisture content of about 17%. Mechanically dried clay also has a diameter of no more than 2 in. (5 cm), but it has a moisture value of about 10%. In 2002, shredded and mechanically dried forms represented about 31% of the market and had an average value of \$34/t. Air-floated clay is powdered and has a moisture percentage of no more than 3%. In 2002, air-floated clay represented about 40% of the market and had an average value of \$54/t. Slurried clay is shipped in liquid form and consists of about 60% clay and 40% water. Slurried clay represented about 29% of the market and had an average value of about \$43/t in 2002 (Virta 2004). Reserves of ball clay in the United States at current consumption rates will last far more than 150 years.

Geology

Overview

The sedimentary environments into which ball clays were deposited appear to vary greatly. As a result, the physical characteristics of ball clays vary greatly. In Tennessee, many deposits are narrow and curved; in cross section, they appear to be river-channel shaped (Figure 4). These deposits are typically surrounded on the sides and undersides by cross-bedded sands and occasionally fine gravels. Clay deposits of this type generally are dark brown and have tan clay on both the top and the bottom of the deposits (Figure 5).

Figure 3. Percentage usage of ball clay produced in the United States

Thicknesses of the deposits vary from 10 to 50 ft (3 to 15 m). Channels are typically about 300 ft (91 m) across and from 500 ft (152 m) to almost 1 mile (1.6 km) long. Deposit sizes range from 2 to 50 acres (1 to 20 ha) (McCuistion 1995).

Other Tennessee and Kentucky deposits are much larger and not confined to channels. These deposits can cover 100 or more acres (40 ha or more), but they do not have a typical lensoid shape. The clays in these deposits are mostly gray but grade into brown clay that is crisscrossed with root structures at the tops of the deposits. These deposits are commonly capped by 2–8 ft (0.5–2.5 m) of lignite with a contact that undulates a few inches with the underlying brown clay. These deposits also range from 10 to 50 ft (3 to 15 m) in thickness (McCuistion 1995). Most other types of deposits fall somewhere near or between the two extremes.

Occurrence and Origins

By far, most of the ball clay produced in the United States is shipped from the Kentucky–Tennessee region (Henry, Weakley, and Carroll counties in Tennessee; Graves County in Kentucky). Significant amounts of clay are also shipped from Panola County in Mississippi and from Cherokee County in Texas. The Tennessee, Kentucky, and Mississippi deposits are all located in the Middle Eocene Claiborne Group (Ackerman 1996), which is near the edges of the Mississippi Embayment (Figure 6). The economic clay

deposits in Texas are in the Lower Eocene Wilcox Formation (Fisher et al. 1965).

The environment in which these clays were deposited is generally considered to be on a fairly flat plain traversed by low-gradient, aggrading streams that occupied broad, flat valleys. Seasonal flooding caused major channels to shift paths, leaving behind abandoned, low-energy environments known as “ox bows.” These abandoned channels or oxbows became ideal low-energy environments for the deposition of fine-grained clays. It is conceivable that the larger deposits not confined to a channel are large-scale overbank deposits.

Two theories exist for the origins of U.S. ball clay sediments. The first is that Porters Creek Clay in the Middle Paleocene weathered to kaolinite and was transported a relatively short distance to its current locations (Hughes, Moore, and Reynolds 1993). The second is that the deposition of these sediments was the result of the Appalachian River system entering the Mississippi Embayment in Kentucky and meandering back and forth across this wide plain (Potter and Dilcher 1980). Both theories are worthy of more thought and further study.

Mineralogy and Properties

The two major components of ball clay are kaolinite and quartz. Many of the properties important to end users are tied to the relative percentages of these two minerals. The variations in composition can be quite large. In five profiles sampled from working clay pits by McCuistion (1995), the quartz contents ranged from 21% to 64% and the kaolinite contents ranged from 33% to 80%. Hughes, Moore, and Reynolds (1993) confirmed that much of the kaolinite present in these clays is mixed-layered kaolinite–smectite. Well-ordered kaolinite represents 37%–67% of the kaolinite within these clays. The kaolinite–smectite component has approximately 88%–99% kaolinite layers (McCuistion 1995). Hughes, Moore, and Reynolds (1993) examined many different deposits and stated that the kaolinite–smectite in ball clay had >80% kaolinitic layers. The presence of this poorly crystallized kaolinite contributes to the plasticity for which ball clay is so well known. Trace clay minerals present in ball clays include illite, smectite (discrete), chlorite, and other mixed-layer clay species. Other trace minerals are mica, pyrite, ilmenite, magnetite, tourmaline, and zircon (McCuistion 1995).

The physical properties of ball clay are as varied as their mineralogies, and the variations significantly affect the end uses of the ball clay. Ball clays have the following properties:

- Moisture content between 18% and 22%
- White, various shades of gray and brown, black, tan, pink, and all shades in between

Figure 4. Cross section and isopach map of a ball clay deposit. Deposit is a clay lens within the Claiborne Formation sands and appears river-channel shaped.

Figure 5. Photo of a mine with tan clay overlying dark brown clay

- Particle sizes between 15% <0.5 μm and 65% <0.5 μm
- Specific surface area (SSA) between 8 m^2/g and 40 m^2/g
- Carbon content from 0.1% to >3%
- Sulfur content from <10 ppm to as much as 7,000 ppm
- With aging, sulfate content from between 200 ppm and 5,000 ppm

- Residues on +200-mesh screens from a trace to 30%
- Deflocculation demands from very low to very high
- Fired color can be white, peach, or pink
- SiO_2 from 50% to 70%
- Al_2O_3 from 18% to 35%
- Average Fe_2O_3 close to 1%

Technology

Exploration

Exploration involves planning, drilling, laboratory testing, and geologic interpretation. Ball clay deposits were originally located by finding outcrops that were visible in topographic lows such as ditches and stream bottoms. Although that method is still useful today, most deposits are generally found well below the elevations of even the most deeply incising streams. Drilling has been conducted in the Tennessee, Kentucky, Texas, and Mississippi regions for more than 75 years. Numerous ball clay deposits have been identified and located but not yet developed. In most of these deposits, the locations, depths, and thicknesses are known, but the only quality information recorded was what the drillers logged in the field (color, sandiness, etc.). Because of the extensive drilling done over the past 75 years, modern planning for exploration involves extensive review of historical records to find tracts of drilled land. Tracts of land that have never been drilled are chosen by proximity to known ball clay deposits and location within the

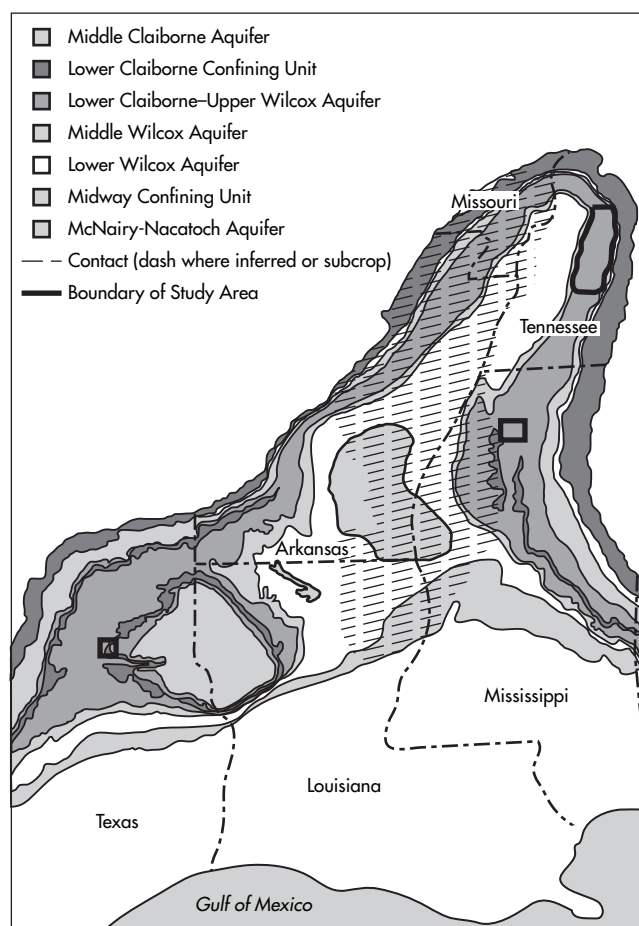

Figure 6. Approximate locations of Mississippi Embayment commercial deposits

general area in which the Claiborne or Wilcox formations outcrop or subcrop.

Ball clay deposits in the United States are now located using truck-mounted core or split-tube sample drills. These drills can recover nearly 100% of the clay encountered. Sampling is typically at 2.5-ft (0.8-m) intervals. Cores are generally 2 in. (5 cm) in diameter. Figure 7 shows a typical rig. Laboratory testing is performed at 2.5-ft (0.8-m) intervals. If an obvious change such as a variation in the color or sandiness of the clay is apparent within that interval, then the sampling interval may be further reduced.

Exploration drilling is done with 150-ft (46-m) spacing between holes. It is necessary to drill this close because some of the deposits may not be much wider across, and drilling at wider spacings could miss some smaller deposits. In most deposits, this distance between holes is sufficient to assess the quality and quantity of the ball clay before removing the overburden. In some smaller deposits and close to the edge of deposits, holes are spaced closer together to ensure quality and to minimize the amount of overburden removal. These holes are then surveyed using either laser-ranging transits or global positioning system (GPS) receivers. Aerial photography is widely used to assist in both exploration and mine planning. This enables sufficiently accurate contouring to be generated to assess both the overburden and reserves in each deposit. Exploration holes are typically drilled to between 75 ft and 100 ft (23 m and 30 m).

Figure 7. Typical truck-mounted drilling rig used in the United States

Each sample representing 2.5 ft (0.8 m) or less is tested for the following properties:

- Particle size (mainly % <20 µm; % <10 µm; % <5 µm; % <2 µm; % <1 µm; and % <0.5 µm)
- SSA (single and multipoint)
- +200 and +325 mesh residue
- Chemistry (mainly SiO₂, Al₂O₃, Fe₂O₃, K₂O, and loss on ignition [LOI])
- Total sulfur or carbon
- Fired color

Composites of samples are given the following ceramic tests:

- Casting rate
- Dry modulus of rupture (MOR)
- Moisture retention

Other application-specific tests may be run on certain individual or composite samples as appropriate.

Most mapping and modeling is now done with computer-aided design (CAD)-based computer programs. If a deposit has sufficient quality, quantity, and overburden ratio to justify development as a mine, then a three-dimensional property map is produced that displays the surface topography and drill-hole locations. After laboratory testing on the exploration samples, a geologist correlates each layer within a deposit between drill holes. Once the property map is produced, then the drill-hole information is entered into the computer to generate a three-dimensional model of the deposit. This model generates geologic tools such as cross sections and isopach maps (Figure 4) to aid in the mine-planning process. Just as important, volumes of individual layers can be calculated for both long- and short-term planning. Volumes of ball clay are transformed into weights by the following relationship:

$$1 \text{ ft}^3 = 100 \text{ lb} \quad (1 \text{ m}^3 = 128 \text{ kg})$$

Mining

Mining involves planning, permitting, overburden stripping, production drilling, actual mining, regular mine sampling, clay aging, and blending.

Mine planning requires the joint involvement of various disciplines. Quality, environmental concerns, and costs are all equally

Figure 8. Overburden is stripped using tractors with self-loading pans

Figure 9. Trackhoes selectively mining individual layers from a Tennessee clay pit

weighted in designing a mine plan to balance all three factors. Mine plans are constructed using the same maps generated by the CAD-based computer programs.

State environmental organizations issue permits. The main federal regulating authority for mine safety is the Mine Safety and Health Administration (MSHA).

Open-pit mining, the method used in all U.S. ball clay mines, requires overburden stripping. The dominant equipment used to remove overburden material is self-loading scrapers or tractors pulling self-loading pans (Figure 8). In particularly wet or soft material, it is sometimes necessary to top-load these pans or scrapers with a trackhoe.

Production drilling is done after the overburden has been removed and before mining takes place. Production holes are spaced 50 ft (15 m) apart to refine mine plans and reserve estimates. The test procedures used in exploration are again used on these production samples. After laboratory testing, the three-dimensional models are updated to make mine plans, cross sections, isopach maps, and estimates of reserves more accurate.

In the United States, the most common equipment used to mine ball clays is the trackhoe (Figure 9). The horizontal and vertical variability inherent in ball clay deposits demands precise mining. Some deposits contain six or more different strata. Each must be mined precisely and stored separately for later blending. The clay is loaded directly onto trucks where it is then transported directly to sheds or intermediate storage areas. Once in the sheds, bulldozers push each load of clay onto its appropriate pile.

Mine samples are taken on a regular basis at the stockpile in the shed. Testing is done to confirm that all steps up through transport of the clay have been performed correctly. If the samples show clay to be out of specification, the clay is either isolated and used appropriately or moved to its proper stockpile. Mine sample data are also used to make precise blends of different clays to achieve a required combination of properties.

Proper aging is important to the deflocculation characteristics of ball clay. Newly mined clays are almost always very difficult to deflocculate. Oxidation and bacterial attack on the mined clay change and degrade the organic matter over time. Sulfate growth is also a result of the aging process and has a profound effect on ceramic bodies. Another benefit of aging is drying; natural drying, in particular, significantly decreases costs.

Blending is a major step in the quality control process. Blending clay reduces variations in products by dampening the natural variation inherent in each strata. Blending also allows adjustment of relative percentages to account for changes in the mine. Blending enables adjustments to be made to control trends or sudden changes in a product that are caused by variations in the clay composition or physical properties. Blending also can create “engineered” products not found in the natural environment as individual strata.

The ball clays are blended in several different ways. Initial blending is done on the floor before loading into the hopper. With this method, the loader operator is given a recipe for the number of buckets of each clay to mix together. With the second method, the recipe is for the number of pounds of each clay to load directly into the hopper. Scales on the hopper guide the operator in this process.

Preprocessing quality control can be summarized in three major steps: drill sampling (premining), mine sampling (postmining), and blending. Figure 10 is a flow chart of this process.

Processing

Ball clay in the United States is processed in dry forms and wet forms (slurry). The flow chart in Figure 10 ends by branching to one of these two processes.

Dry Processing

Figure 11 illustrates the dry-processing technology pathway. Once a blend is batched and mixed together, a front-end loader deposits the blended clay into a hopper leading to a J.C. Steele feeder. The clay exiting this feeder is no larger than a softball. The clay is then carried up a belt to a crusher that further reduces the size of the clay pieces to 1 in. (2.5 cm) or less in diameter.

From the crusher, the clay runs through a dryer that reduces the moisture content of the clay from approximately 20% to about 12%. For mechanically dried product, the clay can be run into a stockpile or loaded directly into a railcar or truck. For air-floated product, the clay is diverted into a mill hopper that feeds clay into a mill that grinds the clay into a powder and dries it further to 3% or less moisture. From the mill, the powdered clay is pneumatically pumped into a hopper. From the hopper, the clay can either be bagged in 50-lb (22.5 kg) bags or pumped into a silo. Trucks and railcars can be loaded directly from the silos or clay can be loaded into 1-t supersacks.

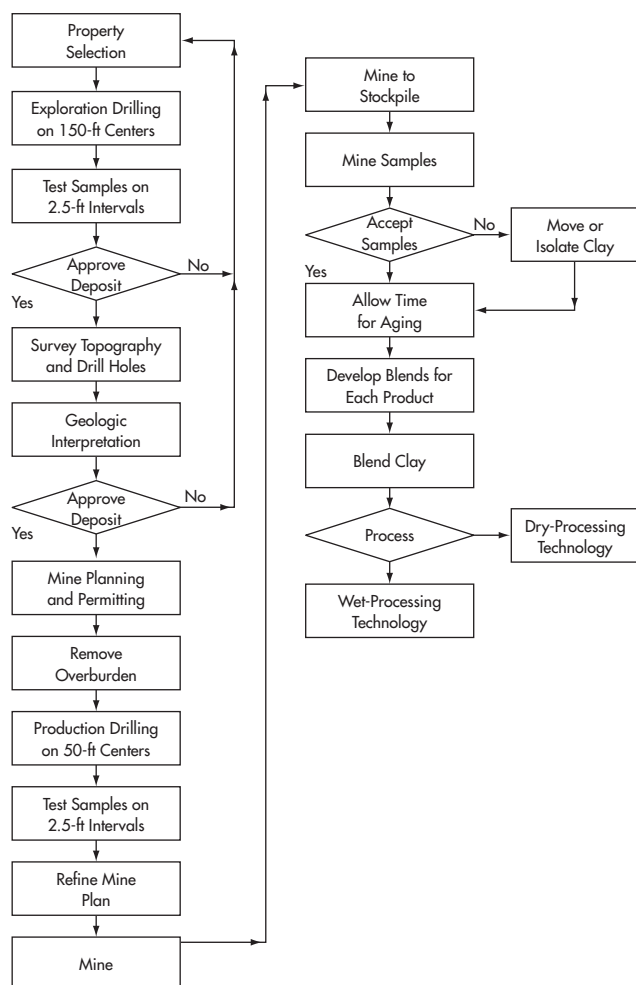

Figure 10. A generalized flow chart for exploration and preprocessing quality control of ball clay

Wet Processing

The other branch of the flow chart in Figure 10 leads to wet processing, which is further illustrated in Figure 12. Instead of blending clay on the floor as is done with dry processing, individual clays are loaded into the hopper by weight. A digital readout on the hopper shows the loader operator how many tons of each clay have been loaded. When the batch is completed, the J.C. Steele feeder feeds the clay onto a belt in softball-size or smaller lumps and into a crusher that crushes the clay into lumps 1-in. (2.5 cm) or less in diameter. The clay is then fed into a blunger and mixed with water and chemicals. Large blades blend the clay–water–chemical mixture until all the clay has broken down. When blunging is complete, the slurry is then pumped over coarse screens that scalp off the coarser material such as lignite and coarse sand. The slurry is pumped over fine screens that take out even more undesired material. After screening, the slurry is pumped into blend tanks. These blend tanks are checked for quality and consistency and, if necessary, are mixed with other tanks to improve the quality. From the blend tanks, the slurry is pumped in to ship-out tanks where the slurry is checked for consistency a final time before the tanks are loaded into either trucks or railcars.

Marketing

Ceramic Usage

Ceramic usages of ball clays include wall and floor tile, sanitary ware, and miscellaneous uses.

A typical tile body contains 20%–60% ball clay, and the rest is varying amounts of pyrophyllite, feldspar, silica sand, and talc. The ball clay in a tile body enables forming and imparts green strength so that the pressed tile retains its shape throughout the green or forming phase of the manufacturing process. The ball clay also helps the body continue to retain its shape throughout the firing process until a vitreous bond is established through melting and mineral transformations (Worrall 1986). Ball clays used for tile products are typically quite fine and fire white to off-white. For some of the darker styles, dark firing clays are more desirable.

A typical sanitary-ware body consists of 35% ball clay, 15% kaolin, and 50% nonplastics such as feldspar and silica sand. Because sanitary ware is cast instead of pressed, the rheological and viscosity characteristics that ball clay adds to a slip are very important. The ball clay acts as a suspending agent for the rest of the nonplastic materials in a slip so that the coarse, nonplastic materials do not settle out. During casting, the green forming characteristics that ball clay adds to the body become important. Green strength and plasticity are critical to the handling of unfired ceramic ware. Sanitary-ware blends are typically fairly coarse to maintain fast casting rates. The ideal blend, however, includes both fine and coarse clays to better balance the need for both casting rate and strength.

Electrical porcelain, hobbyware, and dinnerware all use ball clay for its plasticity and forming characteristics.

Nonceramic Usage

Ball clays are formulated in a wide variety of nonceramic applications such as coatings (interior and exterior), rubber, adhesives, sealants, fiberglass, and fire-retardant systems. Depending on the application, the fine particle size of certain ball clays offers the following processing characteristics or advantages: rheological modification and stabilization; bonding strength; desirable oil absorptions; extrudability; reduced sag and increased stiffness; pigment reduction; improved surface appearance; tack reduction; and controlled drying. Ball clay blends can be engineered to address specific processing needs, resulting in process and quality improvements for the end user.

Economic Factors of the Ball Clay Industry

Exploration and Mine Development Costs

No surface features signal that ball clay may be present on a particular tract of land. Therefore, it is necessary to drill hundreds of holes to find a potential deposit of economic ball clay. Once a deposit is found, it is necessary to drill 100 or more holes to properly characterize a deposit. Additional cost is involved in testing and recording data, interpreting the data, and creating three-dimensional models and mining plans. Permitting also incurs significant costs. A permit for a new mine can take 3–6 months to complete and be approved. Ball clay companies typically have 7–12 mines in some stage of development, mining, or reclamation at any given time.

Stripping, Mining, and Crude Clay Transport Costs

Both contracting and fleets owned by individual companies remove overburden. Costs of overburden removal vary greatly depending on the type of overburden, ratio of clay to overburden, length of haul to a dump site, and amount of water present in the sands.

Ball clay is mined from ground owned by the mining companies and from leases. Minimum payments are made to the landhold-

ers each year until mining begins. When mining begins, the landholders are paid a royalty for every ton removed from the property for purpose of sale. Another cost involves water: it is necessary to pump water continuously from most ball clay mines to keep both rain and groundwater away from the mining areas.

Both contractors and company-owned fleets truck crude clay to processing plants, usually traveling distances of 5–50 miles (8–80 km).

Processing and Drying Costs

Shredded material costs the least to process because it is run only through a shredder before it is ready for shipment. Mechanically dried material is run through a shredder, but it also runs through a dryer that uses significant quantities of gas or other energy source. Air-floated or powdered materials go through an additional costly step of being almost completely dried in a furnace and powdered in a ball or roller mill. Slurry products are also shredded, but they are introduced into a blunger with heated water and significant amounts of chemicals to break the clay down into a pumpable form.

Product Transport Costs

Ball clay product is transported by truck, railcar, barge, or container ship in North and South America. Transportation costs are significant and often exceed the cost of the product itself.

Customer Support Costs

Ball clay producers offer total support to customers and have teams of ceramic engineers that work directly with customers at their plants to help a customer with both production problems and efficiency issues. These teams of engineers discuss the problems and issues with the production facilities so that products can be adjusted to better suit a customer's needs.

BALL CLAY DEPOSITS OUTSIDE THE UNITED STATES

Europe

Ball clay is found in many countries in Europe; major production is in the Czech Republic, France, Germany, Spain, Turkey, Ukraine, and the United Kingdom. Figure 13 is a map of the ball clay deposits in Europe (for this chapter, Europe refers to western and eastern Europe, Ukraine, and Turkey).

Czech Republic

The main ball clay producing regions in the Czech Republic are in Cheb, Pilsen, Most, South Bohemia, and Western Moravia. Production of ball clay was 400,000 t in 2003, with the best-quality ball clay in the Cheb Basin where it is mined in the Nova Ves, Karel, and Vackov areas. These clays are characterized by fine particle size, very good plasticity, white firing, good MOR, and relatively low iron and titania.

France

The two principal clay-producing areas of France are the Charente Basin, worked by AGS, and the Provins Basin. Pornon et Cie SARL is part of WBB Minerals (Sibelco Group) with operations in the Allier region. Here Pornon manufactures selected plastic clay blends for sanitary ware (SanMix PT-28) and for refractory applications (Carat PT-13).

Germany

Clays are mined throughout Germany, but by far the most important region for the production of plastic clays is the Westerwald region. The Westerwald region is situated between Frankfurt and Bonn,

Figure 13. Map of the ball clay deposits of Europe

and the main basin is divided into a number of topographic and generic basins that are controlled by earlier fault patterns. Clay-bearing sequences were laid down in subsidence hollows in the Tertiary period, some 25–40 Ma.

The largest company in Germany is WBB Fuchs, which extracts and processes a wide range of plastic clays and kaolins from deposits in the Westerwald region and other areas of the country. Fuchs'sche Tongruben (Fuchs-Ton) was established as a family company in 1838 and grew into one of the country's leading clay suppliers, becoming part of the WBB Group in 1974. WBB Fuchs-Keramische Massen is a market leader in prepared ceramic bodies, with two dedicated plants at Ransbach and Kannenbäckerland in Höhr-Grenzhausen. WBB Fuchs produces approximately 2 Mtpy. A large range of ball clay products come from the Westerwald; these consist mainly of disordered kaolinite, illite, and quartz with good forming properties and range from red-firing to white-firing clays. The Italian floor-tile market accounts for more than 30% of the Fuchs Westerwald ball clay sales. This market, however, has been attacked by increasing imports of ball clay from Ukraine. Clays having good plasticity and high strength are also sourced from the Eifel region.

Spain

Ball clays used in Spain are mainly domestic (67%) with the rest imported from the United Kingdom, Germany, France, and Ukraine (Regueiro 2004). Total ball clay consumption in Spain

reached 1.2 Mtpy in 2003 and was worth about €36 million (2003 currency; Sanchez and Regueiro 2004).

Formed in 1999, WBB España SA is the market leader in the supply of red-firing clays to the Spanish ceramic tile industry. WBB extracts more than 4.5 Mt of clay, kaolin, and silica sand annually from four main quarries: Sant Joan de Moró near Castellón, Galve near Teruel, and from Madroño and La Yesa near Valencia. WBB also has two other smaller operations in the Castellón Area—Morella and El Campillo—and a kaolin and silica sand plant in Higuera de las Torres near Valencia. WBB España's clays are relatively low in calcium carbonate content and are ideally suited for the manufacture of single-fired floor tiles. The Spanish ceramic tile industry uses almost all of the output from WBB's quarries and produces about 650 million m² of tiles each year; the industry is in the Castellón region.

Euroacre, a subsidiary of the Samca Group, is the major ball clay body producer operating in Spain. The company developed a wet-purification system to produce 115,000 tpy for use in sanitary ware, glazes, and engobes, and has its own spray drying plant with a capacity of 475,000 tpy of ceramic bodies for floor and wall tiles. Euroacre has a quarry in Teruel that produces about 600,000 tpy of ball clays using a very selective extraction technology. These are ground and blended in a 350,000-tpy homogenization facility to produce illitic-kaolinitic clays for the ceramic industry. Minera Sabater is the second Spanish producer from three quarries in Teruel, reaching 250,000 tpy. Potome produces 90,000 tpy of ball clays consumed

exclusively in their factories. Smaller producers are Acrimuso, Minesa, and Minera Capilla, all with operations in Teruel.

Turkey

Ball clay producers in Turkey include Esan Eczacibasi Endustriyel Hammaddeler AS, Toprak Mining Company, and Matel Raw Material Industry & Trade Company. Matel produces 250,000 tpy of ball and ceramic clays in the northwest of Turkey in the Sile region. Matel also has a refined product plant in Bileci. Toprak also has operations in the Sile region and produces 300,000 tpy, mainly for floor and wall tiles. Esan produces about 150,000 tpy of ball clays and also imports clays from Ukraine.

Ukraine

Ukraine has become an important supplier of ball clay over the last two decades with production now reported at about 3.5 Mtpy. One of the companies, Donbas Clays JSC, was established in 1995 and is a joint venture between WBB Minerals and Ukrainian clay producers, YUG. Production increased dramatically from 70,000 t in 1996 to 660,000 t in 2001. Today Donbas exports premium quality white-firing plastic clays to customers in 20 countries around the world. In 2002 Donbas became the first Ukrainian ceramic raw material supplier to achieve the globally recognized ISO 9001 quality assurance standard. The production site in Mertsalo vo has Ukraine's first purpose-built covered storage area; it can hold up to 100,000 t of clay. A rail link straight into this storage unit enables fast and direct supply. Ukrainian clay deposits are characterized by very thick overburden (up to 148 ft [45 m]) and relatively thin clay seams (6.5 ft [2.0 m]), making extraction much heavier work than in other parts of the world. In creating a new quarry area at the South October deposit, an innovative technique for stripping overburden was developed using tractors with scraper pans; it has proved to be about 2.5 times faster than conventional methods.

WBB currently quarries four clay deposits: Yuzhno-Oktiabrskoye, Kucherov-Yarskoye, Novostepanovskoye, and Novoshveytskoye. This represents almost 11 Mt of reserves, and each year WBB prospects to identify new deposits.

Another company is Keramet Private JSC, which mines ceramic clays throughout the Druzhkovka Donetaka region of east Ukraine. The company produced approximately 500,000 tpy of ball clay in 2003, of which 80% was exported to Italy. Exports from Ukraine have grown rapidly because of their suitability for the manufacture of Gres Porcellanato tiles. The clay is characterized by high strength, fine particle size, and particularly low water absorption. When blended with Turkish feldspar, it makes an excellent blend for tiles and is particularly suitable for fast firing.

United Kingdom

The U.K. production of ball clay in 2002 was approximately 1.0 Mt from which sales were 0.92 Mt. U.K. ball clay sales had been on a rising trend for many years and reached a record 1.1 Mt in 2000. Of the 0.92 Mt sales in 2002, 20% was for U.K. customers and 80% was exported. Domestic sales were down from 337,000 t in 1980 to 158,000 t in 2002, partly reflecting the increasing overseas competition that the U.K. whiteware industry has been facing, notably in the tiles and tableware sector (British Geological Survey 2004).

Only two companies produce ball clay in the United Kingdom, WBB Devon Clays Ltd. (now WBB Minerals Ltd., part of the Belgium group Sibelco) and Imerys Minerals Ltd. (a French group formerly operated by ECC International Ltd.). For WBB Minerals, nearly 98% of ball clay products are sold into ceramics, with sanitary ware, tiles, and brick being the three most important sectors. Economic deposits of high-quality ball clay deposits in the United

Kingdom are confined to three areas in southwest England, the Petrockstow Basin in North Devon, the Bovey Basin in South Devon, and the Wareham Area in Dorset.

Ball clays have a limited distribution in the United Kingdom and globally. After the establishment in Devon and Dorset of ball clays consultation areas in the 1940s and 1950s, and the granting of widespread permissions, there are extensive reserves. The consultation areas are designed to ensure that other forms of development do not sterilize clay-bearing land. Table 3 shows estimates of permitted reserves of ball clay for the three basins.

Overall there are large reserves of ball clay, particularly in Devon. The Bovey Basin has by far the largest permitted reserves and unpermitted resources of the three basins, together with the greatest diversity of clays. It will continue to be the major source of ball clay in the United Kingdom for the foreseeable future.

The 921,000 t sold in 2002 was from the following basins:

- Wareham Basin, Dorset: 167,000 t (Imerys sole producer)
- Bovey Basin, South Devon: 661,000 t (WBB and Imerys producers)
- Petrockstow Basin, North Devon: 108,000 t (WBB and Imerys producers)

In Devon, palynological dating indicates that the clays were deposited in the Oligocene epoch (28–35 Ma). They are linked with fault-bounded, tectonic basins associated with the Sticklepath-Lustleigh fault zone, which has resulted in the accumulation and preservation of several hundred meters of ball clay-bearing sediments. The paleoenvironment of the Bovey Basin area during the Paleogene period was a broad floodplain containing seasonal shallow lakes, swamps, and fluvial outwash fans. Thick lignites are associated with the ball clays and formed from floating rafts or mats of vegetation. The Petrockstow Basin shows evidence of cyclothems, and the commercial ball clays are restricted to shelf areas in the northwest and southeast parts. In Dorset, the ball clays of the Wareham Area are dated to the Early to Mid-Eocene (40–50 Ma). They occur in distinct seams up to 5 m thick in host clay sequences that were deposited over a wide area in the lower reaches of a large, eastward-flowing, meandering river system in the western part of the Hampshire Basin.

Dorset ball clays are renowned for their high plasticity and green strength. Because of the relatively low amounts of coloring oxides, they are white to ivory when fired. Clay seams exhibit extensive lateral and vertical variation in chemical and physical properties, representing the variation through time of the source materials and the local depositional conditions. Generally clays become more illitic eastward, as would be expected with the greater marine influence. In Dorset, some 26 clay types are worked from the various seams in the host clays. All the kaolinite in these clays can be characterized as highly disordered with very fine particle size, frequently 90% <1 µm. In the Bovey Basin, significant differences exist in the mineralogy and ceramic characteristics of the ball clays from the various geological members. The Abbrook Member clays have more disordered kaolinite and micaceous mineral than the clays higher in the sequence, which gives a higher green strength and plasticity and a cream fired color. This might represent the exposure and weathering of the nearby Dartmoor granite, giving more kaolinite in the upper levels. The overlying Southacre Member clays are carbonaceous and have a higher percentage of well-ordered kaolinite. The laterally equivalent Chudleigh Knighton Member clays also contain well-ordered kaolinite and exhibit the weak, nonplastic, but white-firing characteristic of sedimentary kaolin. The ball clays in the Petrockstow Basin are basically two types: Type 1 contains appreciable quantities of montmorillonite,

Table 3. Estimated reserves and resources of U.K. ball clay in 2001

Basin	Permitted Reserves, Mt	Years	Resources Unpermitted, Mt	Years
Bovey	63.1	114	16.7*	34
Petrockstow	8.8	37	32†	136
Wareham	2.5	11	9.6	40
Total	74.4		58.2	

Adapted from British Geological Survey 2004.

* Only resources in the east of the basin. There is also potential in the central and western parts of the basin.

† Permitted but not fully explored.

resulting in high defloculant demand values and relatively high slip viscosities; Type 2 contains relatively little monmorillonite and consequently has lower deflocculant demand values and lower slip viscosities.

Table 4 summarizes the mineralogical composition of ball clays from the three U.K. deposits.

In the United Kingdom, some higher-value-added products are often based on wet refining and screening. Some dry grades may be a blend of five to six different components, often from different areas.

Table 5 gives the main types of ball clay, their properties, and utilization for Imerys Minerals in the United Kingdom. Table 6 lists the commercial properties of some of the products from the three areas.

The biggest constraints on future U.K. ball clay development are environmental concerns. It is very difficult to get permission for new ball clay extraction sites. This is especially so in Dorset where there are outstanding international and national habitats covering much of the ball clay consultation area. Also, the greatest constraint on ball clay extraction, particularly in Dorset, is the extent of European nature conservation designations (Special Areas of Conservation and Special Protection Areas), which restrict and potentially sterilize large parts of the Wareham Basin. There is also a multiplicity of both international and national nature conservation designations. Of the total resources in Dorset, some 65% are constrained by nature conservation and other designations. The habitats created after ball clay extraction, in many cases, provide alternative biodiversity benefits.

South America

Argentina

The San Julian Area of Patagonia contains sedimentary clays of Quaternary age that are exploited as ceramic kaolins and used as a ball clay substitute. There are 70 prospects in the area, of which several are being mined. The Tehuelche mine in San Julian has three distinct layers of clay that are mined selectively. The qualities of the layers differ little apart from the amount of carbonaceous (lignite) material present. The clay exhibits a gray to white matrix, the color depending on the carbonaceous content, and consists of kaolinite and fine-grained silica.

Brazil

Several small producers are mining so-called ball clay in Brazil, especially in the Sao Paulo region. All the clays, with a few exceptions, can be classified as ceramic kaolins rather than the true ball clays, and it is often necessary to blend one or two of the different clays to arrive at a suitable ceramic body. The Sao Simao is the best known and exhibits a wide range of fired brightness values. The

Table 4. Mineralogical composition of UK ball clays from three deposits, wt %

Mineral	Petrockstow Basin	Bovey Basin	Dorset
Kaolinite	33–68	20–90	20–83
Quartz	15–48	0–60	5–60
Mica	0–22	0–40	0–30
Organic matter	0–3	0–16	0–8

Table 5. Imerys U.K. ball clay types, main properties, and utilization

Type of Ball Clay	Main Properties	Utilization
Hycast	Good fluid properties	Sanitary ware
Hywhite	High fired properties	Tableware
Hymod	High strength	Tiles, electrical porcelain
Hyplas	Strong and plastic—siliceous	Tiles, electrical porcelain

principal clay mineral present is kaolinite. Free quartz varies from 3% to 24%, accounting for more than 90% of the remaining minerals. Mica content is low: the kaolinite–mica ratio is close to 20:1. Traces of montmorillonite are present and 1% is gibbsite. The clay shows a reasonable MOR, good casting concentration, and casting rates with low deflocculant demand and thixotropy.

Other ball clays are found in the Santo Amaro and Suzano areas. These clays are finer grained than Sao Simao and have higher strength and plasticity but also have the disadvantage of containing considerable amounts of free quartz. They are fairly open burning with low alkalis and good fired colors. Gibbsite is a common constituent in these clays but appears to have little effect on their good rheological behavior.

Africa

G&W Base & Industrial Minerals (Pty) Ltd. is the main ball clay producer in South Africa with 10,000 tpy from the Albertinia mine in West Cape Province. The ball clay consists of a dark, carbonaceous material and a light-colored clay. The two clays are blended 50:50 at the mine, stockpiled, and dried in the sun. Milling is carried out in Johannesburg where the powder clay is bagged. The majority of the clay is sold as a milled product. Further processing is limited because the clay contains very fine quartz, making it difficult to cyclone. The clay has a good green strength and is used in tiles and sanitary ware. The ceramic and tile market is growing in South Africa.

Asia and Oceania

Asia and Oceania is the fastest growing market in the world, mainly as a result of the tremendous growth in the Chinese economy. Also there has been a tendency for European ceramics producers to close some of their production facilities in Europe and move them to this region. Ball clay deposits are operated and being developed in China, Thailand, Vietnam, Indonesia, and Malaysia, among other countries (Figure 14).

Australia

The three main deposits in Australia are in Victoria State, and production is as follows:

- Axedale—about 50,000 tpy, mainly for floor tiles, roof tiles, and pavers. The quality of the Axedale ball clay allows road freight to New South Wales customers, and some is also exported to New Zealand.

Table 6. Properties of typical ball clays in production in 2003 in the United Kingdom

	Ball Clay Deposits						
	Bovey	Bovey	Bovey	Petrockstow	Petrockstow	Wareham	Wareham

* na = not available.

Figure 14. Producers of some ball clay deposits in Asia

- Rowsley—about 15,000 tpy, mainly for local ceramics and also air-milled for the rubber industry.
- Morwell—about 6,000 tpy, mainly for sanitary ware in Melbourne; the ball clay horizon occurs between brown coal deposits.

China

WBB has been active in China for a long time and is now part of the Sibelco Group. They have carried out a great deal of exploration in China and recently acquired the Gilfair Company, which produced some 600,000 tpy of ball clays for a wide range of markets. Some small amounts of high-quality ball clay from the United Kingdom are still imported, particularly for use in sanitary ware. China is the world's leading producer of sanitary ware and tableware, so the search for high-quality ball clays continues in many parts of the country.

India

India has large resources of ball clay-type material, particularly in the Gujarat Area where Ashapura Minichem Ltd. produces 60,000 tpy. Other producing companies are Ambika Overseas Pvt. Ltd., Bhavani Minerals, and Mahavir Minerals Ltd.

Indonesia

There are a number of ball clay prospects in Indonesia, and the main one is PT Clayindo, part of the Sibelco Group. The ball clay concessions of the company are 100 km north of Pontianak (on the equator) on the island of Kalimantan (formerly Borneo). Geologically, the sequence is 4–5 m of overburden with a sequence of 10 m of light creamy brown ball clay interbedded with sandy horizons. A typical result from the area shows a fired brightness of 74, absorption of 17.5, and contraction of 3.7 at 1,120°C with iron and titania levels at 1.1 and 1.2 wt %, respectively. The silica level of 55% is reflected in the mineralogy of 73% kaolinite, 8% mica, and 19% quartz. The clay is suitable for a wide range of ceramic applications, particularly sanitary ware.

A number of ball clay deposits on the island of Belitung are being developed.

Malaysia

The largest producer in Malaysia is Unisil, which controls more than 90% of the market with up to 500,000 tpy, mainly destined for tile manufacture (locally called homogeneous tiles, which are the equivalent of gres porcellanato). The main tile producers are in Johore State with GTI (Kluang) producing 50,000 m²/day. Other producers are MML, Yilai, and Niro. The ball clay deposits are mainly situated near Kuala Lumpur, with recently discovered deposits in the Langgor Area. The Langgor Area shows extensive deposits of ball clay, which are being exploited for their sanitary-ware potential. The “B” grade clay is being exported to Taiwan and Thailand. A 20-t container for Taiwan is approximately US\$45–\$50/t CIF (cost, insurance, and freight). Up to 300 tpm are also being sold in containers to Thailand for use in tableware. The clays can be described as low-carbon, kaolinitic ball clay of medium particle size and low plasticity. The clay has low combined iron and titania, 2.2%, but alkalis are higher at about 3%. It has reasonable fired properties with 75 reflectance at 1,120°C. Rheology shows reasonably fluid clay, with the casting concentration reflecting the fine end of the PSD range. Carbon and salts are low.

The clay has potential in sanitary ware and possibly earthenware. The low carbon would make it suitable for fast-firing applications, though the low strength may detract from its use in tiles unless combined with more plastic ball clays. In general, its properties would lend themselves to a number of uses if suitable other ball clays and kaolins could be found to be a match to particular applications.

Recent exploration in Sarawak identified a series of ball clays over- and underlying coal seams in the Mukah Basin. These deposits are attracting attention from international companies because they show some potential for tiles, sanitary ware, and tableware. They are similar in quality to the ball clay deposits of the Pontianak region of Kalimantan.

Vietnam

Vinacerglass Imex is a member of the Vietnam Ceramic and Glass Corporation and is responsible for all resources for the country's glass and ceramic industries. It is interested in developing the Truc Thon ball clay deposit near Hanoi for the local sanitary-ware market.

The deposit was developed in 1964 to extract clay for refractories, and it was later realized that the clay was suitable for the developing sanitary-ware market. The area is geologically well studied and has been split into 500-m² blocks for development. The resource is given as 7 Mt of clay (includes ball clay and clay for refractories). The clay is present in a floodplain area, and the depth of clay is fairly shallow. A typical cross section is given in Table 7.

The ball clay seam is mined with local tubs, and much is sold in lump form. Some of the grade “A” ball clay is dried in the sun and bagged. There is much foreign investment in Vietnam—Inax, Kerat, Johnson, Ceasar, Laufen, and American Standard have sanitary-ware production in the country.

Thailand

WBB (Sibelco Group) and Imerys (in a joint venture with Banpu) have ball clay operations in the northern part of Thailand in Lampung Province. The Imerys deposits are at Maetan and occur as secondary deposits, laid down in seams derived from sedimentation of the weathered Triassic-rhyolitic tuffs of the region. There are 22 clay seams in the area that exhibit a range of properties from carbonaceous to siliceous ball clays with varying degrees of plas-

Table 7. Typical cross section of a floodplain area

Thickness of Horizon, m	Type of Material
4–5	Alluvial sands and soils (waste)
3–4	Colored clay (for bricks), 14–18% Al ₂ O ₃
2–3	Ball clay, 25–28% Al ₂ O ₃ ; Fe ₂ O ₃ 1.4–3.5%
1–2	Black clay, 22–25% Al ₂ O ₃ (not used)
Varies	Refractory clay, 25–28% Al ₂ O ₃

ticity and iron content. The raw-component clays are selected and mined from an open pit. The range of products is based on their casting rate, plasticity, and chemistry. Grades such as Sancast and Thaiplas S1 are produced for local markets and also some for export.

OUTLOOK AND FUTURE TRENDS

Ball clay production has steadily increased over the past few years and should continue to do so as ball clay producers look for new applications for their clays outside the ceramic industry. The ball clay industry within the United States faces little competition from imports because of transportation costs and the quality of the materials.

Bentonite

Don Eisenhour and Franz Reisch

The term *bentonite* was first proposed by Knight in 1898 after he had originally named this clay *taylorite* after the site of the original mine at the Taylor ranch near Rock River, Wyoming. The name bentonite is from the Benton Shale, the formation within which the clay was thought to have occurred. The Benton Shale is named after Fort Benton, Montana, located more than 640 km to the north.

Several geologists in the early 20th century recognized that bentonite, found predominately in Cretaceous and Tertiary sedimentary rocks, was deposited as transported volcanic materials. This observation resulted in a definition based on origin. A widely quoted definition that is accepted by many geologists is the following by Ross and Shannon (1926, p. 77):

Bentonite is a rock composed essentially of a crystalline clay-like mineral formed by devitrification and the accompanying chemical alterations of a glassy igneous material, usually a tuff or volcanic ash; and it often contains variable proportions of accessory crystal grains that were originally phenocrysts in the volcanic glass. These are feldspar (commonly orthoclase and oligoclase), biotite, quartz, pyroxenes, zircon, and other various minerals typical of volcanic rocks. The characteristic clay-like mineral has a micaceous habit and facile cleavage, high birefringence and a texture inherited from volcanic tuff or ash, and it is usually the mineral montmorillonite, but less often beidellite.

This definition presents difficulties when applied to bentonite as an industrial mineral because it is based on origin and restricts the precursors of bentonite to ash, tuff, or volcanic glass. According to this definition, deposits that consist primarily of the clay minerals montmorillonite or beidellite but are of other than volcanic origin should not be called bentonite. However, many montmorillonite-rich deposits throughout the world that have non-volcanic origins are mined and sold as bentonite. Therefore, commercially, bentonites are defined exclusively on a mineralogical basis.

Grim (1973) gave the most widely used commercial definition of bentonite in a plenary lecture at the International Clay Conference (Association Internationale pour l'Etude des Argiles [AIPEA]) in Madrid, Spain. According to this definition, used in this chapter, bentonite is a clay consisting of essentially smectite group minerals, regardless of occurrence or origin. This definition

allows the inclusion of smectite clays that are sedimentary or hydrothermal in origin and are derived from nonvolcanic parent materials.

Bentonites are generally classified as either sodium (swelling) or calcium (nonswelling) based on their interlayer cations and corresponding ability to swell in water. Bentonites with Na^+ as the predominant exchangeable cation exhibit a high swelling capability in water, whereas bentonites with Ca^{++} as the predominant exchangeable cation exhibit much lower swelling ability. The term *sub-bentonite* was proposed to denote a low or moderate swelling bentonite, but it has largely fallen into disuse and is not recommended.

Within the United States “western bentonite” and “southern bentonite” are often used interchangeably with sodium and calcium bentonite, respectively. This terminology originated because the majority of calcium bentonites within the United States are located in the southern states of Mississippi and Alabama, and the higher-swelling, natural sodium bentonites are located primarily within the western states of Wyoming, South Dakota, and Montana. Other descriptive terms are based on bentonite grade such as high-yield and 13T, which have their origins in the drilling and foundry industries.

Not all bentonites fit easily into these common definitions. Some bentonites, especially those from Turkey and Australia, have Mg^{++} as the major exchangeable cation and are nonswelling in their natural form. Others, especially those with near-surface exposures that are covered with vegetation, have H^+ as their predominant exchangeable cation and are nonswelling. When dispersed in water, these natural H^+ bentonites can exhibit pH values as low as 4 (Knetchel and Patterson 1962). This is much lower than the pH of most calcium or sodium bentonites, which are typically between 8 and 10 in water.

Another type of bentonite, referred to as the potassium type, K-bentonite or metabentonite, is found in Ordovician and other Paleozoic rocks. This bentonite consists mainly of illite and mixed layer minerals and is generally assumed to have formed from volcanic ash. Smectite minerals are present only in minor amounts. This bentonite type contains significantly more potassium than the other types. The meta prefix is included in the name to denote the idea that this bentonite is the product of low-grade metamorphism or diagenetic alteration. The only known attempt to use K-bentonite was in 1928 when five or six cauldrons were mined near Dayton, Rhea County, Tennessee, for purifying lard (Gildersleeve 1946).

HISTORY AND USE

Most of today's major uses of bentonite were developed in the 20th century. In the United States bentonite finds major uses in iron ore pelletizing, drilling muds, pet litters, and foundry sands (Table 1). Overall, global consumption follows similar trends to U.S. consumption, with the exception that use in pet litters is less, especially in developing countries. Significant secondary uses include waterproofing and sealing applications, animal feed additives, oil and grease absorbents, agricultural carriers, and filtering, clarifying, and decolorizing agents. Still smaller specialty uses of bentonite include asphalt emulsions, catalysts, paints, plastics, inks, greases, cosmetics, and pharmaceuticals.

The use of calcium bentonites can be traced back as early as 5000 BC, when they were used to cleanse and thicken woolen cloths in Cyprus (Robertson 1986). It is from this ancient use that calcium bentonites derive the name *fuller's earth*.

In the last century it was discovered that some calcium bentonites are effective at decolorizing or "bleaching" vegetable, animal, and mineral oils (Nutting 1943). This is especially true when calcium bentonites have been acid activated to improve their bleaching efficiency (Rich 1960; Torok and Thompson 1972). Acid-activated bentonites have grown in use relative to unactivated bentonites, especially for oils that are more difficult to bleach or when more highly refined oils are desired.

As used today, fuller's earth is a general descriptive term for clay or other fine-grained earthy material that is used in bleaching,

absorbent, and other related applications (for more details, see the chapter on fuller's earth in this volume). The name does not carry any specific mineralogical or compositional meaning and applies equally to minerals such as attapulgite and sepiolite. Each of these different minerals, however, is not equally suited to all applications in which fuller's earths are used. Premium products for decolorizing edible oils are largely based on acid-activated calcium bentonites.

In the United States, mining of natural sodium bentonite began in 1888 on the Taylor Ranch near Rock River, Wyoming, and in 1903 a mine was opened in Upton, Wyoming, within the bentonite beds surrounding the Black Hills. Mining of calcium bentonite began on a significant scale in the United States in Mississippi in the early 1930s (Bicker 1970). Today there are five major producers and 10 production facilities in Wyoming and South Dakota.

Significant use of bentonite as a sand bonding agent in foundries and as a drilling mud in the oil industry began in the late 1920s. The suspension and fluid loss control properties of western bentonites make them especially suitable for water-based drilling applications (Darley and Gray 1988). As a bonding agent in greensand molding, bentonite has the advantage of producing good compressive strengths when wet or dry (Anon. 1962, 1963, 1994; Sanders 1973). The natural sodium bentonites from the western United States also perform well at the elevated temperatures encountered during the pouring of molten iron and steel, resulting in good clay utilization and fewer casting defects.

Natural sodium bentonites from the western United States are recognized worldwide as performance standards for drilling, foundry, scoopable pet litters, geosynthetic clay liners (GCLs), and in a variety of other applications. These western bentonites continue to be used in markets worldwide despite the availability of local alternatives. This is especially true in applications where technical performance is essential.

Western bentonites are exported to Europe, Australia, and Chile for use in wine clarification. Significant quantities are exported to Europe and Asia for use in GCLs where long-term low permeability is desired. Many regional regulations require the use of western bentonite for GCLs in environmental and civil engineering applications. A number of public and private organizations are studying whether natural sodium bentonites are always superior in GCL applications or whether sodium-activated calcium bentonites can be engineered to achieve similar performance. For less demanding applications, sodium-activated calcium bentonites are commonly used in GCLs today.

Two other applications where western bentonites are widely used in export markets are foundries and oil-well drilling. For oil-well drilling, few bentonites in the world meet the demanding specifications set forth by the American Petroleum Institute (API) for nontreated, section-5 bentonite (Anon. 1993). For the less demanding grades, sections 4 and 6, regional sources are more commonly used. Iron and steel foundries use western bentonites to produce large, heavy-section castings. The superior thermal durability and hot strength of western bentonites are believed to be responsible for their performance advantages (Sanders and Doelman 1968).

Related to the use of bentonites for clarifying oils is their use in clarifying juice and wine. The colloidal nature and high surface area of montmorillonite are exploited in these applications to remove proteins and other submicron substances that contribute to color and opacity. Other mineral filtering aids such as silica sand, diatomaceous earth, and attapulgite work well for removing coarse particles but are relatively ineffective at removing suspended colloidal matter. For clarifying wines and juices, sodium bentonites are used much more frequently than calcium bentonites. Although local bentonites are available, wineries in Europe, Australia, Chile, and elsewhere prefer U.S. natural sodium bentonites because of their superior performance.

The ceramics industry uses bentonites to modify the flow properties of glazes and as plasticizers and extrusion aids in forming ceramic bodies. In the manufacture of both ceramics and refractories, bentonites are used at levels of 0.5% to 3.0% to improve green strength properties. Bentonites added to refractory gunning mixtures assist with sag control.

Bentonite finds some use in modifying the rheological behavior of water-based inks and paints, although attapulgites and organic modifiers are also commonly used. Organically modified bentonites are in wide spread use in oil-based inks, paints, and greases. In both water-based and oil-based applications, bentonite is used to impart anti-drip and anti-sag characteristics. It is also employed as a suspending agent for mineral pigments to improve package stability. In cosmetic and pharmaceutical applications, bentonite serves a similar function to that in inks and paints: It acts as a suspending agent in shampoos, lotions, and gels, and its high yield strength and pseudoplastic behavior allow for the creation of fluids that do not drip or run but flow easily when a spreading force is applied.

Because of their high surface areas and unique surface chemistries, bentonites have been used as catalysts in a number of chemical processes. One common application is the recovery of benzene, toluene, and xylene (BTX) compounds through UOP's (located in

Des Plaines, Illinois) Isomar process. In this process, acid-activated clay typically facilitates the recovery of para-xylene, but can also be used to enhance ortho-xylene and meta-xylene recovery as well. Smectites treated with transition metals such as copper and iron catalyze other reactions. Balogh and Laszlo (1993) describe a variety of reactions using clays, including electrophilic aromatic substitutions, addition reactions, elimination reactions, aromatization, hydrogenation, dehydrogenation, cyclization, Diels-Alder reactions, isomerization, dimerization, rearrangements, condensation, and amino acid and peptide formation under prebiotic conditions.

Cairns-Smith and Hartman (1986) describe the potential role of smectite clays in the formation of life. According to this interesting hypothesis, smectite clays may have been responsible for building the more complex molecules needed for the formation of life on earth.

PRODUCT SPECIFICATIONS

Among the industry standards available for bentonites are those used in drilling muds, foundries, absorbent granules, oil bleaching, cosmetics, and pharmaceuticals. Some standards are widely adhered to such as API standards for oil and gas drilling and United States Pharmacopeia (USP) standards for cosmetics and pharmaceuticals, whereas others such as those for foundry bentonites issued by the Steel Founders' Society of America (SFSA) are followed less rigorously. For most applications, a combination of individual customer requirements and supplier capabilities largely determine specifications. Some testing methods and specifications are described hereafter, by application.

Foundry

The SFSA provides specifications for sodium bentonites to be used as binders for mold and core sands or in preparing mold and core washes. These specifications are described under SFSA Designation 13T-86 (Anon. 1986), and bentonite products meeting these specifications are commonly referred to as 13T bentonites. The technical requirements under 13T are as follows: (1) the product moisture must be between 6 and 11 wt %, (2) the pH value must be equal to or greater than 8.2, (3) the green compression strength must be 15 psi or greater at a compactability of 46 to 51 for agreen-sand mixture containing 7% bentonite and 2.3% to 2.6% water, and (4) the methylene blue exchange capacity must be equal to or greater than 90 meq/100 g of bentonite.

In addition to standard technical requirements, SFSA 13T-86 also provides supplementary requirements that apply only if specified by the foundry customer. These include (1) a maximum exchangeable calcium content of 25 meq, (2) a liquid limit of between 600 and 850, and (3) a bulk density less than 50 g/qt.

The State Mechanical Industry Ministry of China issued foundry bentonite standards JB/T 9227-99 in 1999 (Wen 1998). These standards specify grades of bentonite based on wet tensile strength and green compression strength (Table 2).

Neither the SFSA nor Chinese foundry bentonite standards are widely adopted by foundries exactly as written. Nevertheless, they do provide good guides to the types of properties that are important and minimum requirements that are expected. In almost all cases, competitive products must meet or exceed these standards.

Drilling Mud

Specifications for bentonites supplied to the petroleum industry are set by the American Petroleum Institute under API Specification 13a (Anon. 1993). Specification 13a sets forth requirements for three grades of bentonite under sections 4 (bentonite), 5 (nontreated bentonite), and 6 (Oil Companies Materials Association [OCMA]

Table 2. Chinese foundry bentonite specifications (JB/T 9227-99) issued by the State Mechanical Industry Ministry in 1999

Based on wet tensile strengths (WTS)				
Grade	Moisture,* % maximum	Dry Size, <200 mesh	Methylene Blue Absorption, g/100 g minimum	WTS, kPa minimum
WTS-25	12	95	20	>2.5
WTS-20	12	95	20	2.0–2.4
WTS-15	12	95	20	1.5–1.9
WTS-5	12	95	20	0.5–1.4
Based on green compression strengths (GCS)				
Grade	Moisture,† % maximum	Dry Size, <200 mesh	Methylene Blue Absorption, g/100 g minimum	WTS, kPa minimum

† Moisture specification 15% maximum in winter.

grade bentonite). Additional specifications in the United Kingdom can be found from the OCMA (Anon. 1969).

Section 4 (bentonite) requires rheological properties to be measured in a suspension of 22.5 g of bentonite added to 350 g of water. The dial reading at 600 rpm on a direct indicating viscometer must exceed 30, with a maximum yield point/plastic viscosity (YP/PV) ratio of 3. Filtrate volume must not exceed 15 cm³ and the amount of 75- μ m grit must be less than 4 wt %. Small additions of polymer extenders are permitted provided that all section 4 test requirements are met.

Section 5 (nontreated bentonite) requirements are measured in a suspension of 25 g of bentonite added to 350 g of water. Based on 600 and 300 rpm viscometer readings, the YP/PV ratio must not exceed 1.5. Sodium hexametaphosphate is then added to the suspension and the dispersed plastic viscosity and filtrate volume are determined. Minimum values of 10 cps for dispersed plastic viscosity and 12.5 cm³ for dispersed filtrate loss are required. The specific test procedures and specifications for API section 5 bentonite have been designed to ensure that high viscosities have not been achieved through enhancement with polymer extenders. Section 5 requirements further specify the absence of chemical additives.

Section 6 (OCMA grade bentonite) is described by the API as a bentonite that by the nature of its source cannot meet all the requirements of section 4. It may be treated with soda ash, polymers, or other chemicals to improve suspension performance. Rheological properties are measured in a suspension of 22.5 g of bentonite in 350 g of water. The 600 rpm dial reading on a direct indicating viscometer must exceed 30, with a maximum YP/PV ratio of 6. The filtrate volume must not exceed 16 cm³ and the amount of 75- μ m grit must be less than 2.5 wt %.

Iron Ore Pelletizing

A number of tests have been used to determine the suitability of bentonites for iron ore pelletizing (Davison 1969; Sastry and Fuerstenau 1971; Stone, Karpinski, and White 1971; Wakeman 1972). The most direct tests measure the wet and dry strengths of pellets formed by mixing iron ore powder with bentonite and water. Typically, however, producers of iron ore pellets run these direct tests more than bentonite suppliers.

The most common test used by suppliers to determine the suitability of bentonite for iron ore pelletizing is plate water absorption. This test measures the water absorption ability of a 2-g sample of bentonite placed on a porous sandstone plate in water. In North America and Europe the test is typically run for 18 hours. The amount of water absorbed is expressed as a percentage of the weight of the initial bentonite sample; for example, if 2 g of water are absorbed by the 2-g bentonite sample, the water absorption is 100%. Plate water absorption values greater than 800% are desirable. In China, IOP specification JC/T 592-1995 requires a 2-hr absorption test with a minimum value of 150% required for the highest grade, P-Q-1. In addition, the Chinese standard also requires a minimum free swell value of 15 mL/g for grade P-Q-1.

Other desirable bentonite qualities are low levels of volatile elements such as Na and K, low Si, low Cr and Ti, and high Fe. Na and K contribute to slag on the walls of blast furnaces, Si contributes to the overall slag content in the melt, and Ti and Cr alloy with iron. High iron is desirable because it contributes to iron yield rather than to slag. In North America, bentonites are typically supplied as a milled powder with 70% passing a 200-mesh screen. In Asia, products are supplied as powders milled to between 95 and 99% passing a 200-mesh screen.

Absorbent Granules

Specifications for absorbent granules provide for size, resistance to attrition, and absorption ability. One source of guidelines is provided in Federal Specification P-A-1056A, *Absorbent Material, Oil, and Water*. In the early 1970s, the American Society for Testing and Materials (ASTM) published similar specifications under C431-65, *Standard Methods for Sampling and Evaluation for Sorptive Mineral Products Used as Flo or Absorbents*, which has since been withdrawn.

In general, absorbent granules should be between 6 and 80 mesh in size, have a solubility of less than 1.5% in distilled water, and have the ability to absorb 0.8 mL of lubricating oil (or 0.9 mL of distilled water) per gram. Weidhaas and Brann (1955) describe some special tests for insecticides and other uses.

Bleaching Clays

Bench-scale tests using an approved standard as a reference determine the abilities of both natural and acid-activated bleaching earths to decolorize oils. Official natural bleaching earth standards are approved by the American Oil Chemists' Society (AOCS). The AOCS also provides testing guidelines under Official Methods Cc 8f-91, *Evaluation of Bleaching Clays and Absorbents*; Cc 8e-63, *Modified Bleaching Test for Soybean Oil*; Cc 8a-52, *Bleaching Test (cottonseed oil)*; and Cc 8b-52, *Bleaching Test (soybean and sunflower oils)* (Anon. 1998).

Specialty Applications

Bentonites are used in a variety of cosmetic and pharmaceutical applications as a thickener, a suspending and gelling agent, and a binder. Bentonites used in these applications must conform to the guidelines set forth by the USP/NF (National Formulary) (Table 3) (Anon. 2004). The two basic classifications for USP/NF products are bentonites and magnesium aluminum silicates. Bentonites are specified as dioctahedral smectites and magnesium aluminum silicates are mixtures of both dioctahedral and trioctahedral smectites.

Products in the dioctahedral category are classified as either bentonite or purified bentonite and are manufactured from montmorillonites. The magnesium aluminum silicates are subdivided into four grades, three of which (Types 1A, 1B, and 1C) are distinguished primarily by their viscosities. The fourth grade, Type IIA,

Table 3. USP/NF smectite specifications

Type	Al:Mg Ratio	Viscosity, cps	Pb, ppm (maximum)	As, ppm (maximum)	pH	Glycolated XRD (001)	Acid Demand, mL (maximum)	XRD* (060)
Magnesium aluminum silicates								
Type 1A	0.5–1.2	225–600	15	3	9.0–10.0	15.0–17.2	40	di/tri
Type 1B	0.5–1.2	150–450	15	3	9.0–10.0	15.0–17.2	40	di/tri

Type 1IA	1.4–2.8	100–300	15	3	9.0–10.0	15.0–17.2	15	di/tri
Bentonite	—	—	40	5	9.5–10.5	15.0–17.2	—	di
Purified bentonite	3.5–5.5	40–200	15	3	9.0–10.0	15.0–17.2	40	di

* di = dioctahedral smectite, di/tri = mixture of dioctahedral and trioctahedral smectite.

is distinguished by its lower acid demand and higher Al:Mg ratio. The magnesium aluminum silicates are produced by blending montmorillonite with either saponite or hectorite. Although color is not specified by the USP/NF, these products are typically white with Hunter brightnesses greater than 85.

Bentonites are used in a wide range of other specialty applications. Specifications for these are typically negotiated between customers and suppliers and are not dictated by national or trade association standards.

MINERALOGY

Smectite

The predominant mineral component of bentonite is smectite, which is responsible for bentonite's unique physical and chemical properties. The smectite group minerals include beidellite, montmorillonite, hectorite, nontronite, and saponite. Each mineral in the smectite group shares structural similarities but varies in chemical composition. Powder x-ray diffraction is particularly useful in identifying these various smectite minerals (Moorhead and Reynolds 1989).

Structure

The structure of the smectite minerals is an octahedrally coordinated oxygen layer situated between two tetrahedrally coordinated silicon layers (Figure 1). These individual tetrahedral-octahedral-tetrahedral (TOT) layers are roughly 1 nm thick and are loosely held together by charge-compensating interlayer cations.

The smectite minerals are divided into two groups, dioctahedral and trioctahedral, depending on whether all three octahedral sites are occupied (trioctahedral) or only two are occupied (dioctahedral) (Güven 1988). The dioctahedral smectites montmorillonite, beidellite, and nontronite have the theoretical formula

where M^{+} represents the exchangeable cations. The theoretical formula for trioctahedral smectites such as saponite and hectorite is

Both classes of smectites display elemental substitution within the octahedral and tetrahedral sheets, and it is this substitution that is in part responsible for their unique physical and chemical properties. The magnitude and distribution of surface charge are largely determined by the number and type of substitutions within the tetrahedral and octahedral layers. The replacement of higher charged cations with those having lower charge, for example, the substitution of Al^{3+} for Si^{4+} , results in a net negative layer charge. This negative charge is counterbalanced by loosely held surface cations that are readily exchangeable.

Figure 1. Structure of smectite

Exchangeable Cation Chemistry

The most common exchangeable cations in smectites are sodium, calcium, magnesium, hydrogen, and potassium. Along with the exchangeable cations, water molecules also exist between the TOT layers. The type of exchangeable cation present influences the nature of this interlayer water. Sodium allows one or more layers of water in the interlayer space whereas calcium allows only two layers.

The ability of smectites to exchange cations is described as the cation exchange capacity (CEC) and is typically expressed in milliequivalents per 100 g of clay (meq/100 g). Smectites exhibit cation exchange capacities between 60 and 170 meq/100 g, with values of 100 to 120 being typical. Bentonites commonly exhibit lower CECs than pure smectites because of the presence of nonclay minerals. The exchange capacities of bentonites are influenced by pH and, if iron is present within the structure, Eh (Stucki, Golden, and Roth 1984). Changes in Eh (oxidation-reducing potential) cause iron in smectites to change oxidation state and correspondingly result in changes in CEC.

Figure 2. Western U.S. bentonite outcrop

The influence of iron on oxidation state on CEC can be seen in bentonites in Wyoming and South Dakota. Bentonites in this region can be gray or yellow, depending on the oxidation state of iron. Gray bentonites contain comparatively more Fe^{2+} whereas yellow bentonites are richer in Fe^{3+} . The yellow, or weathered, bentonites have historically exhibited superior colloidal properties. The reasons for this have been a subject of some debate. Knetchel and Patterson (1962) proposed that the superior properties may be related to an increased level of exchangeable calcium. Elzea and Murray (1990) suggest that oxidation of iron results in a reduction in surface charge, a corresponding decrease in exchangeable calcium, and an overall increase in the Na/Ca ratio.

Sanders and Doelman (1968) report observations similar to those of Knetchel and Patterson, that in weathered yellow outcrops calcium levels increase relative to sodium rather than the reverse. Because an increase in Ca/Na ratios appears generally accepted, it is likely that the improved performance characteristics of weathered yellow clays are related to either reduction in layer charge or a process of physical delamination.

The type of exchangeable cations greatly influences the behavior of smectite particles in aqueous suspensions (Foster 1953; Van Olphen 1977; Alther 1986; Lagaly 1989; Wolfbauer 1977). Sodium smectites display greater swelling and superior colloidal properties relative to calcium smectites.

Other Minerals

Other minerals found in bentonite can be classed in three categories: (1) those of volcanic origin, (2) secondary minerals that form in situ as a result of diagenesis and weathering, and (3) those that are of detrital origin. Typical volcanic minerals include feldspars, biotite, quartz, apatite, zircon, magnetite, and amphiboles. Occasionally unaltered volcanic glass is also present.

Minerals of low-temperature origin are poorly ordered opaline silica (Elzea, Odom, and Miles 1994), zeolites, calcite, gypsum, various iron sulfate and oxide minerals, and other clay minerals, including kaolinite and illite. Detrital minerals are the least common and can consist of any rock-forming minerals that are found in sedimentary environments. These minerals rarely exceed 10% of a commercially viable deposit.

OCCURRENCE

Bentonites are found in both marine and non marine environments ranging in age from Jurassic to Pleistocene. These beds can be very extensive geographically, range in thickness from several centimeters to tens of meters, and are usually parallel with the over- and underlying strata. Bentonites also occur as small, lens-shaped deposits. Other less common types of bentonite deposits are those that grade into unaltered host rock.

Bentonites are found in a range of colors, the most common being gray, yellow, olive green, brown, gray-blue, and white. Bentonites have a characteristic soapy texture and waxy appearance. Sodium bentonites often display a typical "popcorn" texture on weathered outcrops. Weathered calcium bentonites have an "alligator skin" texture.

Origin

The most common mode of formation of bentonite is through the in situ alteration of volcanic ash or tuff. A less frequent origin of bentonite is from the hydrothermal alteration of existing igneous rocks. The parent rock type for the majority of bentonite deposits was siliceous and ranged from dacitic to rhyolitic in composition.

The alteration of volcanic ash to smectite is a hydration reaction that requires magnesium and produces excess silica and alkali ions. Bentonite is most commonly found in marine strata, and the alteration of ash in contact with seawater is the most common environment of deposition of commercial bentonites. Other modes of formation include genesis through contact with alkaline lake and groundwaters.

Numerous forms of mineralogical, chemical, and textural evidence show that some bentonites formed through alteration of volcanic ash. Mineralogical evidence includes the observation that bentonite beds often contain euhedral minerals characteristic of volcanoclastic rocks. Chemically the major element and rare earth chemistry of bentonites is consistent with a volcanic origin (Elzea and Murray 1990). Observations under both optical and scanning electron microscopes reveal relict glass shards that have been replaced by smectite. The presence of unaltered glass shards in some deposits provides the strongest evidence of a volcanic precursor.

The time at which alteration of the ash to smectite occurs has been disputed. Theories that alteration of ash begins immediately on contact with seawater and that alteration begins shortly after the ash has settled to the seafloor or lake bottom have been proposed. Others believe that alteration takes place after burial. The Wyoming bentonites have shown to have been altered after burial within the top several hundred meters of subseafloor sediment. This alteration was caused by contact with diagenetic pore fluids evolved from Mowry seawater (Elzea and Murray 1990).

Distribution of Deposits

United States

Western Bentonite. Western or Wyoming bentonite is mined in three major districts in the western United States encompassing Wyoming, Montana, and South Dakota (Figure 2). These districts accounted for more than 90% of western bentonite mined in the United States in 2004.

The Black Hills District is the easternmost of the three districts and production is centered near Colony, Wyoming. This district extends south to Upton, Wyoming, north west to Alzada, Montana, and southeast to Belle Fourche, South Dakota. This area produces high-quality sodium bentonite that is primarily used in the foundry and drilling mud industries. In the past decade a large

amount of bentonite also has been mined for use as scoopable cat litter. Four processing facilities currently manufacture sodium bentonite products from this district.

The central Wyoming district is on the eastern edge of the Big Horn Mountains near the towns of Casper and Kaycee (Figure 2). One plant near Casper processes clay from this area.

The third district is along the western edge of the Big Horn Mountains. Bentonite mines are near Tensleep, Lovell, Greybull, Worland, and Thermopolis, and processing facilities are near Lovell, Greybull, Worland, and Thermopolis.

Western bentonite is mined from approximately eight beds and the majority of these are located within the Cretaceous Mowry Shale. The Mowry Shale is an organic-rich marine shale that was deposited along the Western Interior Seaway. The Mowry Shale is overlain by the Belle Fourche Shale and Frontier Formation, both of which contain commercially exploited bentonite beds. Bentonite is also mined from several beds in older formations in the Big Horn Basin.

All of the Wyoming bentonite beds are interstratified with marine sediments, except for the Newcastle bed mined in the Black Hills District. The Newcastle bed is limited in geographic extent and is believed to have been deposited in fresh water.

Southern Bentonite. Southern, or calcium, bentonite is mined in Texas, Mississippi, and Alabama. The primary uses for southern bentonite are as a bonding clay for foundry sands, a refining agent for oils and fats, an additive for animal feeds, and absorbents. This area is the second most productive bentonite mining district in the United States after Wyoming.

Deposits of southern bentonite are found throughout the Gulf Coast region and are located within formations of Upper Cretaceous to Middle Tertiary age. Commercially developed bentonites in Mississippi are produced from the Eutaw Formation (Upper Cretaceous), the Ripley Formation (Upper Cretaceous), and the Vicksburg Formation (Tertiary). Calcium bentonites mined in Alabama are located in the Ripley Formation. Texas contains extensive bentonite deposits, which are found in the Jackson and Gueydan Formations of Tertiary age.

Fuller's Earth. The majority of fuller's earth produced in the United States is mined from the Paleocene Porters Creek Formation. Processing plants are located along the edge of the Mississippi Embayment outcrop area in an arcuate band from Mississippi north to the southern tip of Illinois and then south through Missouri. The Porters Creek Formation ranges in thickness from 3 to 40 m in the north (Thomas 1981) to up to 150 m in Mississippi (Hughes 1958) and contains an upper weathered zone that is up to 12 m thick. Pyrite is concentrated in the underlying black to dark gray clay (Reisch 1992). Minerals present in this formation are calcium-magnesium smectite, opal C-T, kaolinite, illite, and trace amounts of halloysite and clinoptilolite.

Fuller's earth is also mined in the Miocene Monterey Formation in the southwestern corner of the San Joaquin Valley near Taft, California. The fuller's earth mined here is used predominantly for cat litter and industrial absorbents. Although the Monterey Formation is several hundred meters thick, mining is conducted only in those areas where the bulk density is low.

Other locations where fuller's earth is mined and processed are the Hawthorne Formation near Ocala, Florida, and the Twigg's Clay Member of Barnwell Formation near Wrens, Georgia.

Hectorite. Hectorite is a relatively rare magnesium-lithium silicate with in the smectite group. The majority of hectorite is mined from Tertiary age deposits near Hector, California, which is the type locality for this mineral. These deposits are believed to be altered alkaline lake sediments.

Hectorite is also located in a deposit in Amargosa Valley, Nevada. This deposit is an average of 4.6 m thick, covers a few square kilometers, and contains approximately 25% hectorite and 75% calcium carbonate. West of McDermitt, Nevada, an area consisting of hundreds of square kilometers contains pure to impure hectorite beds and lenses that are associated with volcanic sediments, zeolites, and carbonates; it has been commercially mined since 1986 (Odom 1992).

Other Deposits. Although bentonite production in the United States is predominantly from the Wyoming and Gulf Coast districts, there are a number of small bentonite producers in other parts of the country. Desiccant grade bentonites are mined from a deposit near Chambers, Arizona; this bentonite has also been used as a bleaching earth. Deposits near Vici, Oklahoma, have also been used as desiccant grade material. Sodium bentonite is mined near Adrian, Oregon, and is used in civil engineering and drilling applications. Bentonite deposits in Utah are used in the civil engineering and pet litter markets. Many local producers also supply bentonite for use as a binder in animal feed.

Canada

Bentonite deposits in western Canada are in Alberta, Manitoba, British Columbia, Saskatchewan, and the Northwest Territories. The deposits are found in Cretaceous- and Tertiary-age sediments and are predominant in the Upper Cretaceous marine sedimentary horizons (Grim and Güven 1978). These bentonite beds are often located with shales and limestones and also can occur as partings in coal beds. The Canadian bentonites are predominately calcium bentonites, although they are the same age as bentonites from the western U.S. district. Sodium bentonites are present but are much less common.

Sodium bentonite is mined and produced in Saskatchewan. Commercial products from this area include clays for drilling muds, civil engineering, foundry greensand molding, and animal feeds.

Mexico

Bentonite and fuller's earth are mined in Mexico, primarily in the central region, which contains a large amount of volcanic sediments. Many of the bentonites mined in Mexico are of a mixed calcium-sodium type. Calcium-type bentonites are concentrated in Hidalgo and the majority of sodium bentonite mining is conducted in Durango. Production of both calcium and sodium bentonites totaled more than 415 kt in 1999. In 2004, bentonite production was estimated at 450 kt (Anon. 1995).

South America

Brazil. Bentonite is present in the states of Minas Gerais, Rio Grande Sul, Santa Catarina, Paraíba, Paraná, and São Paulo of Brazil. The majority of these bentonite deposits are not commercially viable because of a high percentage of nonclay minerals. The fairly pure bentonite deposits in the states of Paraná and São Paulo supply more than 90% of bentonite mined in Brazil, which totaled 220,000 tons in 1998 (Russell 2000), making it the largest bentonite producer in South America.

Argentina. Bentonite is found in the provinces of La Pampa, San Juan, Mendoza, Neuquén, and Río Negro of Argentina. Natural sodium bentonite deposits are located in Río Negro and Neuquén. Argentina is the second largest bentonite producer in South America.

Peru. Bentonite deposits are commercially developed in Callao, Ica, and Piura in Peru. Calcium bentonites are the dominant type of bentonite deposit in Peru, although natural sodium bentonite deposits are found in Piura.

Chile. Bentonite mining in Chile is concentrated near Bocanegra, about 60 km east of Arica. Calcium bentonite supplies the local fishmeal pelletizing industry. Acid-activated bentonites are also produced in Lima.

Europe

United Kingdom. Deposits of calcium montmorillonite in England are referred to locally as fuller's earth. These deposits are present in Upper Cretaceous- and Jurassic-age sediments and are mined in Bedfordshire, Oxfordshire, and Surrey.

Germany. Calcium bentonite is extracted in Bavaria from deposits near Mainburg, Mossburg, and Lanshut. These bentonites are located in lenses found in the Oligocene to Miocene section between the Upper Marine Molasse and Upper Freshwater Molasse (Harben and Kusvart 1996).

Greece. The Greek island of Milos contains very large bentonite deposits, some greater than 30 m thick. These deposits have formed by the alteration of Lower Pleistocene volcaniclastics (Christidis and Scott 1996). Along with the United States, Greece is one of the largest exporters of bentonites.

Italy. Bentonites from Italy are mined predominantly on the island of Sardinia and have formed by hydrothermal alteration of trachytes and trachytic tuffs (Grim and Güven 1978).

Spain. Bentonite deposits in Spain are located near Madrid and Almeria. Calcium, natural sodium, and sodium exchanged bentonites are all produced in Spain. Many companies in Spain mine bentonite as a smaller part of their main operations, which involve the production of hormite clays.

Turkey. Numerous deposits of bentonite are present in Turkey, including white bentonites and desiccant-grade calcium bentonites. White bentonites exported to western Europe are mainly used as pet litters and desiccants, and in the production of detergent granules.

Africa

Morocco. The major exploitable bentonite deposits in Morocco are located southwest of Nador and together are estimated to have reserves totaling 1.8 Mt.

South Africa. Bentonite deposits are located in the Koppies district of the Free State and the Heidelberg area of Western Cape. Small deposits are present in the KwaZulu-Natal Province. Acid-activated bentonites are also produced in South Africa.

Australia

The continent of Australia contains many bentonite deposits, including natural sodium. Calcium bentonites are present in Queensland and New South Wales, and sodium bentonites are mined at Gurulmundi in New South Wales.

Asia

India. Indian bentonite reserves contain both calcium and sodium deposits, and the majority of reserves are located in Rajasthan and Gujarat. These bentonites are used for both iron ore pelletizing and foundry greensand molding. Lesser amounts are used for drilling, civil engineering, and pet litters. Indian bentonites are commonly dark red to brown in color and are high in structural iron.

Japan. Bentonite deposits in Japan are of the calcium, sodium, and acid, or hydrogen types. Some white bentonites are of high quality and are used in nanocomposite applications. Almost all bentonites produced in Japan are consumed internally.

China. Bentonite is mined in nearly every province of China; the leading producing provinces are Shandong, Sichuan, and Liaoning.

Bentonite types are both calcium and sodium, although natural sodium bentonites are comparatively rare and of low quality. Mining methods include open pit and underground. Although recent investments by major bentonite companies have resulted in the establishment of larger-scale operations, the majority of bentonite producers are small and local.

DEPOSIT EVALUATION

Exploration

Exploration for bentonite involves using geological knowledge and field investigations. The initial step in exploration is examining the geological environment. An understanding of the basic requirements for bentonite formation narrows the possible settings. Bentonite most commonly forms through the aqueous alteration of volcanic ash. In addition the predominant environment of post-depositional alteration is marine in nature. Bentonites are largely restricted to formations of Cretaceous and Tertiary age. Using these factors, a typical bentonite-forming environment will be an area of past volcanic activity that was located near a substantial body of water.

The next step in exploration is field investigation of a potential deposit. At this time the target area is examined for the presence of bentonite in outcrop. Once the presence of bentonite is confirmed the nature of the deposit is determined via surface mapping combined with drilling. The data from drill logs and maps allow a general assessment of the reserve volume and quality.

After a deposit has been confirmed as viable, other factors are taken into consideration before further expenditure in detailed drilling, testing, and mapping. The thickness of the overburden, distance to major transportation routes and markets, and governmental permitting requirements all must be taken into account.

Mineralogical Evaluation

Examining the mineralogical components of a deposit is an important part of deposit characterization. A thorough understanding of the physical and chemical properties of the clay minerals present will enhance understanding of the deposit, allowing for proper economic utilization. Beneficiation of clays is an increasingly important process as many of the higher quality deposits become depleted. Detailed knowledge of the physical and chemical properties of a clay can be used to design processes for optimum utilization. As higher technology processes continue to be refined, clay minerals are increasingly required to meet more demanding specifications.

Analytical methods used in the study of clay minerals include x-ray diffraction, differential scanning calorimetry, infrared spectroscopy, and zeta potential measurements. Other methods are used to determine particle size distribution, surface area, and interlayer cation chemistry.

Appraisal of Field and Laboratory Results

Bentonite testing consists of a combination of both standard and customer-specified tests. Typical standard tests include rheology testing, as outlined by the API, and foundry bond testing, as specified by the American Foundrymen's Society. ASTM test procedures cover free swell, liquid absorbance, and water permeability. Individual companies also conduct special test procedures designed to satisfy individual customer requirements.

In addition, numerous test procedures are set forth by varying organizations for specialized markets. Examples of such tests are bleaching oil procedures set forth by the AOCS and purity requirements outlined by the USP/NF.

After the relevant data on a deposit are gathered, the information is synthesized with the spatial data on the location of drill

holes. Maps of the deposit are generated, giving a detailed analysis of the deposit that includes clay thicknesses, grades, and overburden depths. This information is used to calculate the expected reserve of the various grades of bentonite. Estimating reserve is one of the first and most important phases of deposit evaluation, but other factors must be taken into account before mining can begin. Overburden amounts and type, distance to processing facilities, transportation issues such as roadways and right-of-ways, and the various legal and environmental permitting requirements all must be accounted for before mining can begin.

MINING AND PROCESSING

Mining

The most common method of mining bentonite is the open pit method. This involves removing overlying material to expose the desired commodity, in this case bentonite. Bulldozers, scrapers, and excavators, and often a combination of these types of equipment, remove the overburden. In a typical bentonite mine the topsoil and subsoil are first removed and stockpiled separately for redistribution during pit closure and land reclamation, and the overburden is then removed. In a typical Wyoming bentonite mine a deposit is mined in stages: After the bentonite is removed from the first area, the overburden from the adjacent area is placed in the void left by the removal of the bentonite and this sequence continues as mining progresses. Scrapers, front-end loaders, or excavators extract the bentonite and load it into trucks for transport to the processing facility.

Western bentonite overburden thicknesses range from zero up to 10 m. Mineable bentonite beds range in thickness from less than 1 m to up to 2 m. A general rule of economic recovery of bentonites requires that the ratio of overburden to clay thickness be less than 10:1, although this ratio may be exceeded where other logistic or market factors are favorable.

Although most bentonite mining uses open pit methods for extraction, some underground mining is practiced. Underground mining methods are used extensively to mine bentonites in Durango, Mexico, and in many locations in China.

Processing

As mined, most bentonites have a moisture between 25 and 35 wt %. Processing the clay usually requires some combination of field drying and plant drying. In arid regions, field drying alone can reduce moistures to less than 12 wt %. Coal-fired rotary dryers are commonly employed at a processing plant when additional drying is required. Final product moistures typically range between 7 and 12 wt %. Care must be taken to avoid overdrying bentonites because this can result in reduced performance.

After drying, bentonites are sized by passing the ore through a combination of roll crushers, screens, and roller mills. Where extremely fine particle sizes are required, air classification is often used either during milling or as a separate stage of processing. Polymers to improve viscosity and fluid loss are typically added either directly before or after milling. Polymer additions vary depending on the application, but levels between 0.25 and 1.50 lb (0.1 to 0.7 kg) per ton of clay are typical. Long-chain water soluble polymers are most commonly used to enhance the performance of bentonites.

Soda ash is typically added either in the field or at the plant before drying. In the field, soda ash is added as stockpiles are built or on clay that has been spread out to dry. Both dry and wet additions of soda ash are common in field operations. Plant additions of soda ash are typically made to wet clay using a paddle mixer to uniformly distribute the components. Water may be added to improve

the reaction between soda ash and clay, but excessive water is avoided because of the higher drying costs associated with higher moistures. In some operations, pug mills and extruders help mix soda ash and clay. The more aggressive mixing by extruders has the added benefit of improving clay performance through mechanical delamination.

For high-end cosmetic and pharmaceutical products, water washing commonly removes impurities and improves brightness. In this process, bentonites in low-solids slurries are subjected to a series of wet screening, hydrocyclones, and centrifugation to remove nonclay impurities. Soda ash additions are made before drying on rotary drums to produce flake products or by spray to produce powdered products. An additional fine milling step sometimes further reduces particle size to less than 20 μm .

To produce acid-activated clays, sulfuric or hydrochloric acid is added to a clay slurry and allowed to react for several hours. Pressure filtration removes residual acid from the clay. An alternative method for producing acid-activated bentonites involves the formation of "noodles," which are then acid-leached and washed without filter presses. The rinsed acid-activated clays are then dried and ground to the desired particle size. Acid activation typically increases Brunauer Emmett Teller (BET) surface areas from less than 10 m^2/g to more than 250 m^2/g . This method of surface area measurement is based on the physisorption and desorption of nitrogen.

ORGANOCLAYS

In the second half of the 20th century it was discovered that smectite clays could be organically modified to make them function well in low-polarity solvent systems such as mineral oils, toluene, xylene, and diesel fuel. The basic technology involves exchanging Ca and Na cations with cationic surfactants, especially quaternary amines. This exchange process converts hydrophilic smectites into those that are organophilic (hydrophobic).

Although both types of smectites (hydrophilic and organophilic) function by delaminating to form colloidal size particles, the mechanisms for dispersion are quite different. In aqueous systems, sodium smectites disperse through the hydration energy of water and are electrostatically stabilized as a result of their negative charges. In contrast, electrostatic and enthalpic forces do not dominate in nonpolar systems, so the primary driving force for dispersion is entropic.

Organoclays have found a wide variety of uses in low-polarity systems, and new applications are constantly being developed. A particular area of recent focus has been the development of organoclays for use as functional fillers in plastics. Numerous commercial applications of clay-polymer composites have appeared in the past few years.

Applications

Paints and Coatings

Organoclays serve three primary functions when used in solvent-based paints and coatings: (1) anti-settling, (2) anti-sag, and (3) anti-drip. In high-end coating applications finely ground wet-process organoclays ensure a smooth and uniform surface finish. In lower-end coating applications such as traffic paints, coarser ground dry-process organoclays are more commonly used. Typical use levels in paints are between 0.3 and 1.1 wt %.

Printing Inks

In printing inks, organoclays provide stable viscosity, control misting, and can improve water resistance. High purity and fine grinds are required in this application. Typical use levels in printing inks are between 0.2 and 3.0 wt %.

Lubricants and Greases

Water-washed organoclays that are free of abrasive grit are used in the manufacture of greases. Organoclays are especially used to thicken high-temperature greases because of their thermal stability. One potential weakness of organoclays in greases is their poor interaction with some corrosion inhibitors. These anticorrosion additives can have a detrimental effect of an organoclay's ultimate viscosity. Typical use levels in greases are between 5 and 10 wt %.

Drilling Fluids

Although both organobentonites and organohectorites are used in oil-based drilling applications, the majority of the volume is in low-end dry-process organobentonites. These low-end organoclays do not require the fine grinding required for paint grades and easy-dispersing grades. The high shearing encountered in the drilling process provides enough energy to disperse even coarser grades of organoclay.

For deep well drilling where greater thermal stability is required, organohectorite is used in place of the more cost-effective organobentonites. Bentone 38 (Elements Specialties, Inc., Hightstown, NJ) is the primary product used in these high-temperature applications. For quite some time Bentone 38 was the only suitable product on the market. Alternatives, however, are now becoming available. Typical use levels in drilling fluids are between 2 and 5 wt %.

Adhesives and Sealants

Organoclays are principally used in adhesives and sealants to prevent running or sag during the drying or setting process. Organoclays are used not only because of their rheological properties but also because they typically do not negatively affect the physical properties of the system. As an example, organoclays are used in polysulphide sealants for the construction industry to maintain slump resistance in vertical joints during curing. Typical use levels in adhesives and sealants are between 1 and 3 wt %.

Ceramics and Refractories

Organoclays are used as a binder in the manufacture of some refractory bricks and monolithics, especially where the presence of water in the binder system is detrimental. An example is calcined dolomite refractories, where an oil-based binder system prevents the hydration of the lime and magnesium oxide.

Organohectorite is sometimes preferred in the manufacture of monolithics because of its higher thermal stability in the range of 200° to 400°C. In some applications organobentonites do not maintain enough viscosity in this temperature range to prevent sag during firing. Higher-temperature thermal stability is a general characteristic of organohectorites. Typical use levels in ceramics and refractories are between 0.3 and 1.5 wt %.

Consumer Products

Wet-process organohectorites and organobentonites are both widely used in cosmetics and personal care products, especially fingernail lacquers, antiperspirants, lipstick, sunscreens, and eye products. Hectorite treated with a trialkylaryl ammonium cationic surfactant is widely used in fingernail lacquers because of the medium-to-high polarity solvents used in their formulations.

This market has increasingly shifted a way from using dry organoclays toward using mastergels. Mastergels are organoclays that have been pre-dispersed in commonly used solvents such as mineral oils, SD 40 alcohol, lanolin oil, cyclomethicone, or combinations of these. Mastergels have grown in popularity in the personal care industry because of their ease of use.

In response to customer requests, organoclay suppliers recently introduced products based on surfactants not derived from animals. Examples include a vegetable-derived quaternium-18 organobentonite and a vegetable-derived stearyl ammonium organobentonite. Typical use levels in personal care products are between 0.3 and 1.5 wt %.

Material Requirements

Organoclay systems require three basic components to function properly: (1) clay, (2) a cationic surfactant, and (3) a polar activator. Conventional organoclays incorporate two components, clay and surfactant, into the organoclay product, and the end user adds a polar activator. Self-activating or self-dispersing organoclays combine all three components, clay + surfactant + activator, in a single product.

Because of the volatility of some polar activators like methanol and acetone, they cannot be incorporated directly into a single product, so self-dispersing organoclays typically contain a different type of polar activator than is used in conventional organoclay systems. Although self-dispersing organoclays offer added convenience, in many applications they also have somewhat lower gel strengths than conventional organoclays. Consequently a number of users still prefer conventional organoclays to the newer, self-dispersing grades.

Clays

The type of clay used in the production of an organoclay is as important for the final performance as the surfactant and the polar activator. No simple correlation appears to exist between a clay's performance as an organoclay and its performance as an untreated, water-based, rheological additive. Consequently conventional tests of free swell, viscosity, cation exchange capacity, and plate water absorption do not directly predict a clay's performance potential as an organoclay.

Bentonites from the Black Hills region of South Dakota and Wyoming have been widely used in the manufacture of both wet and dry-process organoclays. To date, the only commercially available organohectorites are based on hectorite mined from Hector, California.

Surfactants

The majority of organoclays are surface modified by reacting bentonite or hectorite with a tetraalkyl ammonium cationic surfactant. These are used in solvent systems based on mineral spirits, hexane, toluene, xylene, styrene, alkyds, and vegetable oils.

The second most common organoclay surface modification is achieved by reacting a smectite clay with a trialkylaryl ammonium cationic surfactant. This surface treatment produces an organoclay that will disperse in higher polarity solvents than organoclays produced with a conventional dimethyl ditallow quaternary ammonium surfactant. Common systems that use a trialkylaryl ammonium organoclay are epoxies, polyesters, polyamides, polyurethanes, acetone, methyl ethyl ketone, ethyl acetate, ethylene glycol ether, propanol, and ethylene glycol.

Polar Activators

Polar activators facilitate the dispersion of organically modified clays and help achieve stable gel strength and high gelling efficiencies. Most self-dispersing grades either have some form of polar activator incorporated into the organoclay during production or have an excess of surfactant loading. Table 4 lists types of polar activators and typical amounts required based on the weight of organoclay.

Processing

The two basic methods of manufacturing organoclays are dry processing and wet processing. The dry process produces low-end organoclays and the wet process produces high-end organoclays. In both processes, the addition level of surfactant is critical. The optimum level of surfactant is usually between 27 and 34 wt %, although some self-dispersing grades have surfactant loadings >40 wt %. For any given clay, the optimum level must be maintained within $\pm 1\%$ or performance can be degraded. Undertreatment is usually more detrimental than overtreatment.

The drying temperature and final moisture are also important factors. Exposing organoclays to temperatures $>100^\circ\text{C}$ can be detrimental to performance. Similarly, over or under drying can also be detrimental. Optimum final product moisture should be in the range of 1% to 3%.

Dry Process

In the dry process, warm surfactant is added to 200 mesh clay (with or without a small amount of water) to form a dough. For best performance, the dough is thoroughly mixed and (preferably) extruded under high shear. The wet organoclay is then dried and ground to the desired particle size. In addition to reducing grit, grinding to a finer particle size improves the dispersibility of the final product.

Wet Process

In the wet process, the clay is dispersed in water at a total solids level between 2% and 5%. The resulting clay slurry is then hydrocycloned and centrifuged to remove nonclay impurities. In a separate mix tank, the surfactant is dispersed in warm water (50° to 80°C) at a level of 3% to 8%. The surfactant/water mixture is then added to the clay slurry under high shear or strong agitation. The resulting organoclay suspension is then filtered to (a) increase the solids level and (b) remove excess Na and Ca salts produced by the reaction of the surfactant and clay. The filter cake may be washed one or more times to remove additional salts. The cake is then dried and ground to the desired particle size. To improve the rate of dispersion, high-end organoclays are commonly milled to a mean particle size of between 1 and 10 μm .

FUTURE TRENDS

An area of active research in the past decade has been the use of smectites as functional fillers in polymers. In these applications, individual smectite particles are dispersed within a polymer matrix to form a polymer-clay composite material. Because the thicknesses of the dispersed clay platelets are approximately 1 nm, the composite materials formed are commonly referred to as *nanocomposites*.

The steps involved in making smectites suitable for nanocomposites are similar to those for making organoclays for conventional applications such as greases and printing inks. Smectites are beneficiated to remove other mineral impurities and then surface modified with a surfactant to make them disperse within the host polymer. Organoclays designed for use in nanocomposites primarily differ from conventional organoclays in their types of surface modifications and their greater levels of purity. Smectite-based nanocomposites have the potential to improve the thermal and mechanical properties of engineering plastics, increase chemical resistance, act as flame retardants, and decrease the permeability of films.

A number of surface-treated smectite products have been introduced into the market by leading organoclays manufacturers or through alliance partners. The overall use of smectite-based nanocomposites is currently limited but is expected to grow as markets adapt to this new technology.

Table 4. Chemical polar activators commonly used with conventional organoclays

Activator	Percentage*
Methanol (95%)/water (5%)	33
Propylene carbonate (100%) [†]	33
Propylene carbonate (95%)/water (5%)	33
Ethanol (95%)/water (5%)	50
Acetone (100%) [†]	60
Octylphenoxy polyethoxy ethanol [†]	75

* Percentages based on weight of organoclay.

[†] When a water-free polar additive is desired.

Over the past decade, the use of GCLs has continued to show strong growth and new bentonite-based liners continue to be developed. Efforts are being made to extend the effective lifetime of liners and to improve their resistance to a variety of environmental contaminants. Investigations are also taking place to better understand the performance differences between natural sodium bentonites and sodium-activated calcium bentonites. The results of these investigations could influence GCL specifications set forth by regulatory bodies.

A significant amount of research has been conducted on the synthesis of pillared clays (Schoonheydt et al. 1999; Gil, Gandia, and Vincente 2000; Cool and Vansant 2004). The unique mesopore dimensions and high pore volumes of pillared clays have demonstrated potential viability in several adsorption and catalytic applications involving relatively large molecules of high value. Commercial adoption of pillared clay technologies, however, has been slow to develop. This has been in large part because of their high manufacturing cost relative to conventional adsorbents such as zeolites and because of difficulties involved in producing materials that have sufficient selectivity and reproducibility for demanding adsorption and catalytic applications. It remains to be seen whether the unique characteristics of pillared clays will begin to be exploited more widely in commercial applications.

The unique surface chemistries and high surface areas of smectites continue to make them a focus of many research efforts. Their colloidal properties and nanoscale dimensions are likely to be increasingly exploited as emerging technologies focus on nano- and mesoscale interactions and processes.

Common Clays and Shale

Karan S. Keith and Haydn H. Murray

INTRODUCTION

Common clays are a naturally occurring, fine-grained material composed predominately of hydrous aluminum silicates. The term *common clay* encompasses a wide variety of clay types, including fine-grained rocks such as shale. Common clays and shale are a useful geologic material because they typically exhibit plastic behavior when wet. This material can then be formed into desired shapes and fired to produce a product with rock-like hardness. Common clays and shale are the most widespread ceramic materials. Products made from these clays include items such as structural and face brick, drain tile, vitrified pipe, quarry tile, flue tile, conduit, pottery, stoneware, and roofing tile. Large quantities of common clays are also used to make construction materials such as lightweight aggregate and portland cement. They are used as filler in paint and other products, for packing dynamite blast holes, and for plugging oil and gas wells that are no longer in use.

GEOLOGY

Mineralogy

Common clays occur in a variety of environments and in many different rock types across all time periods of the geologic record. The source material includes glacial clay, soils, alluvium, loess, shale, weathered and fresh schist, slate, and argillite. Fireclay and kaolin are sometimes considered common clays, particularly when used in the manufacture of structural clay products. Mineralogically, common clays are highly varied, although the most common constituent is usually one of the members of the mica mineral group. Mica clays include illite, sericite, muscovite, and biotite. Other frequently occurring clay mineral components of common clays are kaolinite, smectite, mixed-layer clays, and chlorite. Quartz and other detrital minerals are typical nonclay minerals present in rocks mined for common clay.

Illite is one of the most abundant clay minerals found in sediments and sedimentary rocks and one of the most prevalent minerals in common clay resources. *Illite*, a term introduced by Grim, Bray, and Bradley (1937), is mica-type clay mineral that was named after an abbreviation for Illinois. Illite is a low-temperature mineral formed at the earth's surface. It is a hydrated potassium aluminum silicate (Figure 1) in which some iron is usually substituted for aluminum in the structure. Illite is similar in structure to smectite, the main difference being that in illite the interlayer cation is potassium and in smectite it is sodium, calcium, or magnesium.

Figure 1. Structure of illite

Because of the similarity in structure, it is common to have smectite interlayered with illite, which is termed a *mixed-layer* clay. Smectite is an expandable clay, and if the mixed-layer clay material contains significant quantities of smectite, its presence can lead to excessive shrinkage during drying, in addition to other problems.

Clays and shale from the Pennsylvanian strata in the central and eastern portions of the United States have an excellent range of properties for making structural ceramics and low-grade refractory shapes. Commonly these strata have a refractory underclay or fireclay beneath a coal bed and a red-firing, illite-chlorite-rich roof shale above the coal (Hughes 1993). The roof shale is sometimes upwashed and coarsening, which allows producers to create shale or fireclay blends

that have adequate plasticity for forming the material. Additionally, there are often enough sand- and silt-size nonclay minerals to open the body and speed burnout during firing.

Physical and Chemical Properties

Common clays have a wide range of physical properties, making them applicable in many different structural products. These physical properties include plasticity, green strength, dry strength, drying and firing shrinkage, vitrification range, and fired color. The properties desired vary with the structural clay product made. For example, clay used in making conduit tile must be very plastic and have high green and dry strengths and uniform shrinkage. These properties do not have to be as closely controlled in manufacturing drain tile or common brick.

Plasticity is defined as the property of a material to undergo permanent deformation in any direction without rupture under stress beyond that of elastic yielding. *Fat* clays are clay materials that have a high plasticity; *lean* clays have low plasticity. Many factors can influence the plasticity of a clay material, including mineralogy, particle size, particle shape, organic matter, soluble salts, adsorbed ions, and the amount and type of non-clay minerals present.

Green strength and dry strength are important properties of clays used in structural applications because most structural clay products are handled in the manufacturing process and must be strong enough to maintain their shape. *Green strength* refers to the strength of the clay material in the wet or plastic state, while *dry strength* is the strength of the clay after it is dried. Dry strength depends on the proportion of fine particles present; the shape of the individual particles; the degree of hydration of the clay fraction; the method of forming the ware; and the rate and thoroughness of the drying. The presence of a small amount of smectite, which occurs in very fine hydrated particles, generally increases dry strength. Green strength is influenced by many of the same variables as plasticity.

Drying and firing shrinkages are critical properties of clay used for structural clay products. *Shrinkage* refers to the loss in volume of a clay material as it is dried or fired. Drying shrinkage depends on the water content, the character of the clay minerals, and their particle size. Most plastic clays shrink appreciably with drying, often producing cracking and warping. Clays with low plasticity, such as sandy clay, have low shrinkage but can produce a weak porous body. An excess amount of smectite minerals (10% to 25%) commonly causes excessive shrinkage, cracking, and slow drying. Firing shrinkage of the raw clay depends on the density of the material, volatiles that are present, the types of crystalline phase changes that take place during firing, and the dehydration characteristics of the clay minerals.

Vitrification (or glass formation) is a process of gradual fusion in which some of the more easily melted constituents produce increasing amounts of liquid as the temperature is increased. This liquid produces glass as the material is cooled, and the glass is the bonding material in the final fired product. The temperature range of vitrification during firing is a very important property of clays and shale used in structural clay products. Some clay has a narrow vitrification range, requiring close monitoring of kiln temperatures during firing. Clays consisting primarily of illite, smectite, or chlorite have a lower vitrification temperature than kaolinite-rich clay. Mineral impurities such as calcite and feldspar lower vitrification temperatures by acting as fluxes. Temperature and duration of firing will determine the degree of vitrification attained. The amount of shrinkage and porosity required in the final product most commonly dictates the extent of vitrification.

Uniform color is an essential property of many structural clay products. The color of a final fired product is influenced by a variety of conditions: the state of oxidation and particle size of the iron minerals; the firing temperature and degree of vitrification; the proportion of alumina, lime, and magnesia in the clay material; and the composition of the gases in the kiln during the burning operation. High-grade white-burning clay contains less than 1% Fe_2O_3 , buff-burning clay ordinarily contains 1% to 5% Fe_2O_3 , and red-burning clay contains 5% or more Fe_2O_3 . Although several factors also affect product color, finely divided iron-bearing minerals are the primary materials influencing color in the final fired product.

Mineralogy of the clay or shale deposit can most easily be determined by x-ray diffraction. The type and proportion of clay minerals present directly influence the amount of iron-bearing minerals in the material. A raw material that is predominantly illite becomes red when fired and gets hard at relatively low temperatures. Products that could be made from this material include red bricks, drain tile, and building tile. The presence of kaolinite in a raw material generally results in material that burns light or white and is hard to fuse. Products made from these clays are light or buff bricks and refractory brick.

PRODUCTION AND MARKETS

Common clays are widely distributed, usually easily located, and are often used in products that do not require elaborate processing. Typically, common clays and shales are dug from open pits, and these pits must be near the processing plants to minimize production costs. Usually both the raw material and the finished products are heavy and the profit margin is low, so production costs must be controlled. Most products made from these materials are processed and marketed in a similar manner to refractory clays. Common clays and shale require little beneficiation. Typically they are crushed or ground only before pugging and extrusion. Physical contaminants such as concretions are removed by dry screening. Beneficiation for clays needed in ball clay or kaolin applications may occur in the form of drying or air flotation. Clays used in refractories are often blended to meet product standards. Figure 2 is a generalized flowsheet for processing clays used to make structural clay products.

In 2003, approximately 160 companies in 41 U.S. states produced common clays and shale. In states not reporting production, common clays and shale probably were mined and sold for construction applications by companies not participating in the U.S. Geological Survey canvass of producers. Common clay production in the United States, at the mine, was 23.2 Mt (a slight increase from 2002) with a value of \$149 million. This increase was the result of strong demands from the construction market. Major domestic uses for common clays are distributed as follows: 56% brick, 17% cement, 17% lightweight aggregate, and 10% other uses.

The average price for all common clays and shale sold in the United States and Puerto Rico in 2003 was \$6.45/t. The price of common clays and shale sold for lightweight aggregate production in 2003 was estimated to be \$13.70/t. The price of lightweight aggregate products ranged from \$30 to \$50/t for most applications.

Leading producer states of common clays and shale in 2003 were, in decreasing order: North Carolina (2.4 Mt); Texas (2.16 Mt); Alabama (2.02 Mt); Georgia and Ohio (1.31 Mt each); Missouri (1.05 Mt); California and Oklahoma (1.03 Mt each); South Carolina (1.02 Mt); and Kentucky (925 kt).

Sales or use of common clays and shale increased to 23.2 Mt in 2003, matching production. The major markets were building brick (12.8 Mt), production of lightweight aggregate (4 Mt), and portland cement clinker manufacture (3.95 Mt). Sales of lightweight aggregate

can be subdivided into concrete block (2.37 Mt), structural concrete (908 kt), highway surfacing (364 kt), and miscellaneous lightweight aggregates (361 kt). Other markets include drain tile, floor tile, flue linings, pottery, refractory products, roofing granules, sewer pipe, and structural tile.

The largest user of common clays and shale is the brick manufacturing industry. Production of bricks increased from 8.47 million in 2002 to 8.6 million in 2003, whereas shipments of brick increased from 8.04 million in 2002 to 8.54 million in 2003. This increase was the result of continued demands from the construction sector.

The demand for clay floor and wall tile also increased in 2003. Production increased from 622,000 floor tiles and 649,000 wall tiles in 2002 to 652,000 floor tiles and 672,000 wall tiles in 2003.

Production of vitrified clay sewer pipe and fittings decreased to 143,000 units in 2003 from 159,000 units in 2002, whereas shipments increased to 151,000 units in 2003 from 139,000 units in 2002. The increase in shipments resulted from using stockpiles for clay pipe and tile products (Virta 2004).

RESEARCH AND TESTING

Developing and testing most common clay products demands preparing test pieces of specific dimension, and drying and firing properties (Klinefetter and Hamlin 1957; Clews 1969; Grimshaw 1972). Fired test pieces are evaluated for shrinkage, warping, cracking, permeability, modulus of rupture, and compressive strength. Color and soluble salt content are also important properties for some clay products.

A collaborative effort between the Illinois Clean Coal Institute, the Illinois Department of Commerce and Community Affairs, researchers at the Illinois State Geological Survey, and local brick manufacturers is ongoing in researching the combined use of coal fly ash and local clays and shale in brick manufacturing. Development of a commercially viable brick product could result in a value-added use for the millions of tons of waste fly ash produced each year.

In 2002 the Illinois State Geological Survey, sponsored by the Illinois Clean Coal Institute, began a 2-year study to locate and map common clays and shale resources that have high potential for use in producing fly ash-supplemented brick. This research was done in an effort to provide a market for fly ash, a by-product of coal-derived power generation, and to expand existing markets. Using by-product wastes such as fly ash generally requires clay materials with a fine particle size. The researchers defined areas that were best suited for development of a clay or shale resource within a 50-mile radius of four major coal-fired power plants in Illinois. Results of this study are under consideration for the possible development of a new brick manufacturing operation that would use by-product fly ash and local clay and shale resources in the brick production process.

REGULATORY CONSIDERATIONS

The U.S. Environmental Protection Agency (EPA) issued its emission standards for brick and structural clay products manufacturing under its maximum achievable control technology (MACT) standards. These new standards are expected to reduce emissions of hydrocarbons, hydrogen chloride, hydrogen fluoride, and trace metals by 2.3 ktpy, a 35% reduction from current emissions. The standards specify acceptable technology for controlling pollution and also limit plant kiln design capacity (Virta 2004).

Figure 2. Typical process flowsheet for structural clay product manufacturing

OUTLOOK AND FUTURE TRENDS

The market in common clays and shale has remained nearly unchanged for the past 5 years. The primary markets for common clays and shale products are residential and commercial construction. Products used in construction include brick, drain tile, lightweight aggregate, quarry tile, and structural tile. Strong growth in these segments should sustain the common clays and shale market for the near future. The demand for other products may fall short of this growth rate. Based on recent growth trends, the sale and use of common clays and shale should remain steady for the next several years.

The market for heavy structural-clay products still faces strong competition from cement, wood, glass, plastics, aluminum, and other metals. Growth in this market is always limited by the heavy weight of these products, which limits their market range and increases production costs. The cost of fuel for transportation can have a major effect on industry growth, and thus the most economical mines and plants are often located near one another and ideally near large metropolitan markets.

Fuller's Earth

Sam M. Pickering Jr. and Fred G. Heivilin

INTRODUCTION

Fuller's earth is a general term for industrially versatile smectite or palygorskite-sepiolite clays (hormites) with high surface area and strong sorptive, binding, gelling, thickening, or decolorizing ability. Fuller's earth has been in common use from perhaps biblical or at least medieval times, when such clays and earths were used for "fulling," or cleaning raw wool to remove greasy lanolin and dirt before the wool was spun, dyed, and woven. The term *fuller's earth*, when used for such a wide variety of industrial clays, has no specific compositional, market, or mineralogical connotation.

Fuller's earths are composed of various combinations of absorptive clay minerals, often with varying amounts of impurities such as silica (at times in the form of fossil diatoms), kaolinite, illite, zeolites, clay-size micas, and carbonate minerals. In general, such clays of marine sedimentary origin in the southeastern United States are commonly called *fuller's earths*, whereas in the American West clays originating by alteration of volcanic ash are typically termed *bentonites*.

Mineralogy, crystallinity, crystal habit and shape, particle size, and crushability are all critical to the sorptive, binding, thickening (gelling), cation exchange capacity (CEC), specific gravity, dusting, deodorizing, and decolorizing abilities of commercial-grade fuller's earth clays. Therefore, these important factors have a profound effect on the refined product's specific industrial uses, market applications, pricing, and customer acceptance.

NOMENCLATURE

Although fuller's earth is a widely used commercial term, it has often been inconsistently applied to a variety of smectites, hormites, bentonites, zeolites, impure diatomites, and other such clay occurrences. The essence of the American Geological Institute's (AGI's) *Dictionary of Geological Terms* definition of fuller's earth is that it is a very fine grained, earthy substance with high water absorptive capacity and ability to refine and decolorize edible oils; it differs from ordinary clay in its higher water percentage and lack of plasticity (AGI 1962). The AGI also applies this term to fuller's earth clays without reference to any particular chemical or mineral composition, texture, or geological origin.

Given that this definition allows considerable overlap that could include many different types and occurrences of other clay materials, more specific fuller's earth definitions may be of interest. Ampian (1985, pp. 158–159) stated that the term fuller's earth "has

neither a compositional nor a mineralogical connotation, and the substance is defined as a nonplastic clay, usually high in magnesium, that has adequate decolorizing and purifying properties." Although the term *nonplastic* is often used, it is seldom specified whether it is applied to fuller's earth clays in the raw moist state, after partial drying or in a semicalcined condition.

In the 6th edition of *Industrial Minerals and Rocks*, Elzea and Murray (1994, p. 234) used the term fuller's earth as "more or less a catchall for clay or other fine-grained earthy material suitable for bleaching and absorbent and certain other uses." In a like manner to the AGI usage, they also state that fuller's earths have "no compositional or mineralogical meaning." Elzea and Murray also gave a historical outline of fuller's earth use, which can be summarized as use in antiquity for cleansing and fulling wool; use by the late 1800s for decolorizing and purifying mineral and edible oils; use in the early 1900s for petroleum processing; and use in the last half of the 20th century as an oil absorbent, cat litter, and agricultural chemical carrier granules, replacing petroleum purification as the dominant use. In the mid- to late 1900s, fuller's earths began to be widely used for adsorptive purposes as either natural or acid-activated clays for bleaching mineral or edible oils (Nutting 1943).

Bentonites are similar clays that may overlap with fuller's earths in both commercial application and mineralogy. To simplify the distinction between the two clay types, however, the AGI (1962, p. 49) defined bentonite as "a clay formed from the decomposition of volcanic ash and is largely composed of the clay minerals montmorillonite or beidellite." They specifically restrict the use of the term bentonite to clay that was "produced by decomposition of volcanic ash and not from the decomposition of any other substances." It is interesting that some southeastern fuller's earth clay producers refer to their products used in the foundry sand market as "bentonites," which may serve to obtain a freight-rate advantage over the western bentonite producer's eastern sales.

Some clay researchers explain the origin of many of the southeastern fuller's earth deposits as wind-blown volcanic ash from the west, but they have never been able to establish a volcanic source for the presence of hundreds of feet of eastern clay deposits. The present authors (also see Merkl 1989) regard the southeastern smectitic-hormitic clay deposits as having been deposited by normal, nonvolcanic sedimentation in quiet water basins under very low energy in highly saline, anoxic-reducing environments.

Table 1. A historical long-term trend record of U.S. fuller's earth production and average U.S. free on board (f.o.b.) selling prices

U.S. Production*	1940	1950	1960	1970	1980	1990	2000
Short tons, <i>st</i> [†]	146	395	407	980	1,529	2,541	3,201
Metric tons, <i>t</i>	133	359	370	891	1,390	1,880	2,910
\$/st	12.21	26.45	22.55	23.73	49.82	88.00	75.09

Source: Buckingham and Virta 2003.

* Note that U.S. production, unlike statistics from other nations, is of actual refined product tons, not crude clay tons.

† All U.S. domestic sales of bulk fuller's earth product are made by the short ton (2,000 lb).

Table 2. U.S. fuller's earth sales by market use, 2002

Market Application	Sales, <i>st</i>
Pet waste absorbent (cat litter)	1,738,000
Oil and grease absorbents	449,900
Fertilizer pelletizing binder	152,900
Pesticide and herbicide carrier	112,200
Animal feed pelletizing binder	89,700
Filtering, clarifying, and decolorizing	69,630
Fillers, extenders, binders, and drilling mud	64,680
Miscellaneous	290,400
U.S. export	33,990
2002 yearly total sales	3,003,000

Source: Virta 2004.

PRODUCTION

U.S. Geological Survey (USGS) published records (Virta 2004) show that worldwide annual 2002 fuller's earth production was some 3,900,000 t, of which the United States produced and sold approximately 70%. As has been discussed, however, nomenclature of industrial smectite and hormite clays is subject to considerable confusion.

In gathering U.S. and foreign mineral production statistics, the USGS, by policy, does not attempt to precisely identify the type of clay being mined but rather classes each mining company's production based only on what the companies themselves report that they mine (R.L. Virta, personal communication). For several examples, the following instances are rather typical:

- Calcium montmorillonite may be referred to as calcium bentonite in some parts of the United States but is called fuller's earth in England (Harben and Bates 1990).
- In the Florida–Georgia fuller's earth district, near the town of Attapulgis, the clay being mined is informally referred to as attapulgite rather than the mineralogically more accepted term palygorskite. Similarly, palygorskite occurs in two very different crystal habits—as “mountain leather” type material in hydrothermal vein environments and as sorptive gelling clay in anoxic-reducing, semimarine sedimentary deposits.
- Attapulgite (palygorskite) and sepiolite may both be reported by the USGS as fuller's earth production in the United States (Heivilin and Murray 1994).
- Calcium montmorillonite may be referred to by the USGS as “southern bentonite,” “Mississippi bentonite,” or “Texas Bentonite,” although there may be little or no evidence of its volcanic origin.
- Large tonnages of sorptive clays produced for cat litter products in Spain and Senegal are variously referred to as sepiolite, meerscham, and attapulgite in the same publication

(Newnan 2003) and as both fuller's earth and attapulgite (Virta 2004).

U.S. fuller's earth production tonnage and product prices (exclusive of bentonites) have grown with the national economy over the past 70 years, as reported by Buckingham and Virta (2003) in thousands of tons and average selling price in Table 1.

The USGS (Virta 2004) lists U.S. production of processed fuller's earth products for 2002 as 3,003,000 st (2,730,000 t), which sold for \$246 million (or an average 2002 price of \$81.92 per processed short ton). This total production was from 12 listed states: 5 companies in Georgia; 3 companies each in Florida, Mississippi, and Nevada; 2 each in California and Virginia; and a single company each in Kansas, Illinois, Missouri, Oregon, Tennessee, and Texas. Additionally, the USGS (Virta 2004) reported U.S. 2002 total fuller's earth sales by generalized market application (Table 2).

Fuller's earth is such a versatile industrial minerals material that many of its commercial uses do not fit conveniently into such simple categories, so this listing should be regarded as reflecting only generalized market segments. Also, by law the USGS is required to avoid listing production statistics for mineral market uses served by only one or two producers because that would divulge confidential production and sales information. This practice has the effect of putting much of specialized production into the miscellaneous category. Similarly, the USGS (Virta 2004) reports estimated 2002 world fuller's earth production from market economy countries (France, India, Iran, Japan, and Turkey unreported; Table 3).

HISTORICAL U.S. PRODUCTION AND PATTERNS OF USE

Native Americans were reported to have used fuller's earth and bentonite for cleaning blankets and clothing before European arrival in the 15th century. During the Revolutionary War, soldiers stationed near Perth Amboy in New Jersey used Woodbridge fire clay to clean their buckskin clothing. In the early 1800s, fuller's earth was discovered in association with an iron ore bed near Kent, Connecticut. During the Civil War, fuller's earth was used to bleach sugar near Falls City, Texas.

The first documented commercial fuller's earth deposit in the United States, which is still being mined today, was discovered in 1893 near Quincy, Florida. The Owl Commercial Co. (predecessor of the present makers of White Owl cigars) made the discovery during their attempt to make burnt brick from clays on their Quincy tobacco plantations. Because of its high content of smectite, the clay was unsuitable for brickmaking. One of the Alsatian farm workers in the area, however, recognized the Quincy clay as similar to fuller's earth, which was being mined in Germany. Two years later, his observation led to development of the first U.S. mine for fuller's earth for processing mineral oils. Also, fuller's earth had been mined slightly earlier on a small scale in Arkansas in 1891 (Miser 1913) and tested for use in refining cottonseed oil.

The U.S. demand for acid-activated fuller's earth for edible oil and petroleum refining and decolorizing expanded rapidly until it

peaked at about 317,000 st in 1930. At that time, this was about 90% of total U.S. fuller's earth production. After 1930, the use of fuller's earth for petroleum refining decreased because of the availability of alternative oil refining methods.

After that time, U.S. oil refining use of fuller's earth declined until it reached a uniform rate of 35,000 to 40,000 st/y for edible oils only. Using fuller's earth as a waste oil absorbent and floor-sweep type of clean-up agent, however, began before World War II and, by the 1950s, its use as a carrier for herbicides and pesticides had become more prominent. Cat litter production began in 1952, and it has grown rapidly since then.

In the district between Quincy, Florida, and Attapulgus, Georgia, the excellent gelling properties of palygorskite (attapulgite) fuller's earth were discovered and developed for salt water drilling mud, as a joint binder taping compound for sealing the seams of construction wallboard, and for other applications requiring a thickened gelling clay. These uses for gelling fuller's earth products developed to replace sales lost when use for petroleum refining declined. The Florida–Georgia mining district today is the world center for gelling fuller's earth clay production.

What is now by far the most prominent American use for fuller's earth, as a pet waste absorbent product (cat litter), began to grow rapidly in the 1950s. At first, cat litter was made from oil absorbent product that had been crushed to finer than $3/4$ -in. size, semicalcined in countercurrent rotary kilns, milled and screened, and packaged for retail sale. Today, cat litter is typically dried to only 4% to 15% moisture, which results in improved absorption, reduced dusting, and lower energy cost.

In the early 1990s, clumping cat litter became very popular. Blending western bentonite or clumping agents with eastern fuller's earth causes liquid waste to form clumps that can easily and neatly be taken from the litter box with a perforated scoop. This leaves only unused clean granules in the litter box, minimizing waste and enabling easy handling of a formerly messy and unsanitary chore. Today, many clumping cat litter products are up to 100% western sodium bentonites.

GEOLOGY

Mineralogy

Typically, fuller's earth is a marine or semi marine sedimentary clay variably composed of the clay mineral groups smectite and hormite. Tables 4 and 5 summarize these closely similar types of clay minerals.

In 1862, Savchenkov first used the term *palygorskite* to define a vein-type hydrothermal "mountain leather" clay mineral from the Palygorsk locality in the Ural Mountains of Russia (Hey 1975), where it was mistaken at first for a variety of asbestos.

J. de Lapparent first termed the highly absorptive gelling clays from Decatur County, Georgia (United States), and also those from an area near Mormoiron, France, with the mineral name *attapul-gite*, because he thought those clays quite different from palygorskite. The new name was applied to gelling clays occurring near the small southern Georgia town of Attapulgus. More recently, however, x-ray diffraction proved the two clay types to be the same mineral (Bailey et al. 1971). Although first applied later than palygorskite, the name attapulgite is still in common informal use in the Florida–Georgia mining district where the crystal length-to-diameter ratio does not exceed 10:1 (Merkel 1989).

In 1774, Glocker first applied the name *sepiolite* for a clay mineral later called "meerschau" by Werner in 1788. Haüy in 1801 described the same type of low-density white magnesium silicate clays as *ecuame de mer*, which Brochant in 1802 also termed *talcum plasticum*. Today, this type of magnesian clay mineral is

* Informally termed attapulgite in the Florida–Georgia, Spain, and Senegal mining districts.

known as sepiolite and is found more abundantly in the northern extent of the Florida–Georgia basin than more southerly concentrations of attapulgite near Quincy.

The reader is referred to the Bentonite, and Palygorskite and Sepiolite chapters of this book for a more detailed discussion of the mineralogy of the smectite group and hormite minerals, respectively.

Origin

Fuller's earth clay deposits in the eastern United States are found in marginal marine sedimentary units that formed in restricted, anoxic, shallow, low-energy, reducing, and often hypersaline conditions. Such depositional environments favor formation of magnesian montmorillonite, palygorskite (attapulgite), or sepiolite.

Alternatively, sorptive calcium montmorillonite fuller's earth deposits have been formed in Nevada in Pliocene freshwater lakes with as much as 40% siliceous diatom tests. In south-central

California, what is now the Miocene Antelope Shale was originally deposited as diatomite and then diagenetically altered by deep burial to a form of absorbent opal CT.

Other inert, nonabsorptive, accessory minerals in fuller's earths can include dolomite, calcite, quartz (sand, silt, biogenic opaline CT, or diatomite), gypsum, and assorted heavy minerals. Finely divided fossil or organic plant matter can color the fuller's earth gray or bluish gray; oxidative weathering alters the clay to a cream, tan, green, pink, or yellowish tint.

Physical Properties

Mineralogy of fuller's earths determines their most effective potential use. Montmorillonite is a type of clay mineral that shrinks when dried and may swell when rewetted. Highly adsorptive when dried, this mineral is used in granular animal litter, in floor-sweeping compounds, and as a carrier for insecticides, herbicides, and so forth.

The extremely fine particle size, high CEC, and tight packing of attapulgite- and montmorillonite-rich fuller's earths make them useful to increase "stickiness" and promote high green strength in ceramic dinnerware; to provide adhesion and plasticity in metal foundry molding sands; as an adhesive binder to form pellets of taconite iron ore, agricultural fertilizers, and so forth; and to form an impermeable seal or slurry barrier for isolation of sanitary landfills and hazardous waste disposal sites.

Bleaching clays with or without acid activation need a particular pore size and porosity to clean and decolorize edible oils. There are only two such actively mined fuller's earth clay deposits in the United States—in northeastern Mississippi where acid activation (the clay slurried with acid) is necessary and in the south Georgia district near Meigs, where clays bleach naturally or with only acid addition to the dry powdered product.

The presence of attapulgite in elongate needle-shaped or acicular habit crystals is indicative of superior gelling or thixotropic behavior when slurried with water or liquid polymers. Such fuller's earths can be used for oil-field drilling muds, which retain their integrity as thick and viscous gels, even in the presence of saline formation brines. Magnesian fuller's earths can also be used in thickened or gelling form to produce nondripping paint, to thicken liquid detergents, for wallboard joint cement and spackle compounds, and for other specialty applications.

In the Florida-Georgia fuller's earth mining district, attapulgite commonly occurs in two distinct forms known as short- and long-length crystalline material. The higher gelling long-length clays are found in the southern part of the district and are stratigraphically restricted to the Mid-Miocene age Dogtown Member of the Hawthorn Formation of northwestern Florida. Dogtown attapulgitites are typically longer in crystal habit than 10 μm and are associated with the most favorable gel-strength clays. The slightly younger Meigs Member clays contain short attapulgite crystals less than 10 μm long and are more prevalent in the northern portion of the fuller's earth mining district in southeastern Georgia near Ochlocknee.

Sepiolite clay also occurs in needle-like crystal habit in the more northerly Meigs Member and remains stable at relatively higher temperatures. Thus sepiolite-rich fuller's earth products can be useful as drilling muds for maintaining borehole circulation when completing geothermal production wells.

DISTRIBUTION OF MAJOR U.S. DEPOSITS

Southeastern United States

Fuller's earth deposits of commercial quality and accessible for shallow open-pit mining are mostly found in several districts in the

southeastern United States, where relatively low-energy, warm, restricted coastal marine conditions were prevalent during late Mesozoic and Cenozoic times.

These southeastern fuller's earths are found in three main stratigraphic formations:

1. In the Mid-Miocene Dogtown and Meigs members of the Hawthorn Formation in the mining district between the towns of Quincy, Havana, and Dogtown in the panhandle of north Florida, and Attapulgus, Reno, Calvary, Cairo, Ochlocknee, and Meigs in southwestern Georgia
2. In the Late Eocene Twiggs Clay Member of the Barnwell Formation in the area east of Wrens in Jefferson County, Georgia
3. In the Late Paleocene Porters Creek Clay between Cairo and Mounds in Pulaski County at the southern tip of Illinois, and in the towns of Ripley and Blue Mountain in Tippah County, Mississippi

The Florida-Georgia District

A narrow depositional trough trends southwest to northeast across the Florida Panhandle region from the town of Quincy to near the Georgia towns of Attapulgus, Meigs, and Ochlocknee (Herrick and Vorhis 1963). This restricted basin, variously termed the Gulf Trough or the Apalachicola Embayment, has localized fuller's earth deposits in the Miocene-age Hawthorn Formation that dominate U.S. production of both granular and gelling-grade industrial clays.

Suggestions have been made that fuller's earth clays in the Florida-Georgia District originated from altered volcanic ash (such as in Reynolds 1970); more recent research (Thomas 1981), however, has shown no indication that these marine and semi-marine clays were deposited in any conditions other than normal, nonvolcanic, reducing environments in shallow sedimentary basins.

Gelling-grade magnesian attapulgite (Figure 1) is much more concentrated in the Dogtown Member of the Hawthorn Formation at the narrowest southern end of the trough or basin; and the smaller percentages of sepiolite and shorter-crystal-length attapulgite- and montmorillonite-mixed clays of the Meigs Member are more abundant toward the northern end. The Florida-Georgia area underlain by this Miocene-age trough has been continuously and extensively mined for various grades of fuller's earth for more than a century.

This depositional trough is thought to have begun as a considerably older graben structure that served as a major ocean current seaway throughout much of the early and mid-Tertiary but was broadly uplifted in the Miocene when much of what is now Florida was raised by the Peninsular Arch (Herrick and Vorhis 1963; Huddleston 1993). During the mid-Miocene, the trough was uplifted and cut off from open ocean circulation; it became a series of discontinuous, small to extensive, evaporitic basins rich in magnesian salts, where dolomitic limestone, attapulgite/palygorskite, and sepiolite were deposited.

The Virginia District

Two fuller's earth producers in east-central Virginia mine a rather heavy, marginal-grade diatomaceous mudstone for cat litter in the Miocene Calvert Formation (Hosterman and Patterson 1992). This material, although not of superior quality, has a considerable freight advantage in shipping to the population centers in northeastern cities.

The Mississippi Embayment District

A wide Coastal Plain sedimentary embayment or open-fronted basin extends inland along the course of the Mississippi River as far

north as Cairo and Mounds, Illinois. This continuous outcrop belt of the Late Paleocene-age Porters Creek Formation from Ripley and Blue Mountain, Mississippi, to Mounds and Cairo contains many fuller's earth deposits that are as much as 370 ft thick.

These Paleocene-age calcium montmorillonite clays have less desirable higher-density and lower-absorbency characteristics than clays from the Florida–Georgia district. Their freight advantage to the large midcontinent market area, however, and their ability to blend with western swelling bentonite to provide good liquid-clumping capacity allow their extensive use in the cat litter trade. Some companies blend the weathered light-colored clays with darker, unoxidized clays to produce an attractive “salt and pepper” colored product from the Porters Creek clay district.

The U.S. Western District

Different types of fuller's earth are produced in the western United States, such as at California's San Joaquin Valley, where absorptive mixtures of opal-CT altered from diatomite are present. Two high-grade fuller's earth deposits in Nevada, composed of mixed montmorillonite and diatomite, have been proven for quality and passed standard validity exams for granular cat litter and oil absorbent, but they have not yet been brought to the market. Some sepiolite gelling clay is found in east-central California, but it is of marginal quality and sold mainly in the West Coast market.

EXPLORATION METHOD

Fuller's earth exposed in surficial outcrops is commonly too weathered and oxidized by soil-forming processes to have sufficient quality for industrial use. New fuller's earth deposits are often discovered by widely spaced core drilling near areas where the clay was mined or near outcrop exposures that look promising.

Truck-mounted rotary drilling rigs of the type developed for placing explosive charges for early oil-field geophysical exploration—such as the 500 and 1250 models built by Failing, Gardner-Denver/Mayhew, and DSM—are used for the drilling depth of 100 to 200 ft common in fuller's earth exploration. Double-tube core barrels with built-up hard metal bits are used, and the core is extruded with water pressure from the drill rig's mud pump or with compressed air. Typically, NX-size core of about 2 1/8-in. diameter is recovered; rinsed and trimmed; marked accurately by property code number, hole grid location, and depth in the hole; and transported in boxes or bags to the company laboratory for extensive quality testing.

When an area of core holes tests favorably in the laboratory, accurately spaced core-drilling campaigns are begun on a surveyed grid of 400 to 800 ft. As the shape, extent, and quality of new clay deposits are proven, grid drilling is narrowed to spacings of 200 and 100 ft before overburden stripping is begun.

After the commercial clay surface is exposed, closer spaced drilling may be done using air-pneumatic or auger methods, or the area may be sampled with a mining backhoe. Regulated wetlands, endangered species areas, and archaeological sites are avoided wherever possible. Lately, however, mitigation is needed for wetland areas that must be crossed by haul roads or those underlain by high-quality fuller's earth that the company wishes to mine.

Fuller's earth quality is posted from drill and laboratory testing results on carefully scaled grid maps, which are used for mine planning, government permitting, and future clay reserve tonnage calculations. These mine planning maps show overburden thickness and type, clay thickness and commercial quality, location of property boundaries, and regulated wetland areas.

Figure 1. Foliate texture of high-magnesian attapulgite gelling-grade fuller's earth from the Florida–Georgia District near the axis of the Gulf Trough depositional embayment. This texture develops shortly after the raw clay is exposed for mining and is thought to be an indicator of high gelling strength. (Knife, for scale, is 10 cm long.)

CLAY QUALITY CHARACTERISTICS

Special Characteristics

The fuller's earth industry, particularly perhaps in North America, has become accustomed to applying special terms to different properties of clays and their products. These terms may not be familiar to those outside the industry, so some simplified explanations may be helpful, as follows:

- *Clumping clays* are those clays with clumping agents or a high content of western sodium bentonite; they have become very popular for clumping or scoopable-type cat litter products. The bentonite absorbs liquid wastes, which clump in discrete lumps that can be neatly scooped from the litter box, leaving only clean litter behind. Bactericides are needed to improve long-term odor reduction in western bentonite clumping cat litters.
- *Dusting clays* are those clays that are unsuitable for granular products because they break down too finely upon crushing or during shipping, handling, or use. In cat litters, a high dusting clay product causes mudging, tracking outside the litter box, and a dirty cat.
- *Heavy or high-density clays* is a term used for cat litter products that are denser than about 40 lb/ft³. These products typically are lacking in absorption, take up more room in the cat

box, are inconvenient for the retail purchaser to carry, and commonly do not control odors as well as lighter clays.

- *Gelling clays* is a term used for clays that have a high slurry viscosity at low percent solids; these clays are used as a thickening agent for wallboard-tape joint cement, nondrilling paints, drilling muds (especially palygorskite, used to maintain circulation when drilling in brine formations), and liquid detergents, and as a fine pulp retention aid in paper manufacture, liquid fertilizer suspensions, adhesives and sealants, putties and glazing compounds, and other industrial applications. Gelling viscosity is typically measured on Fann or Brookfield viscometers. Gelling behavior and viscosity can be enhanced by extruding the moist clay to align the needle-shaped crystallites or by adding calcined magnesium oxide.
- *Granular clays* refers to products that are carefully crushed and screened to a narrow range of chip sizes, often listed such as "4–20" (passing through a U.S. Standard 4-mesh screen and retained on 20 mesh). The granule size controls product surface area and liquid or gas absorption in the animal litter.
- *Slaking clays* are those clays that, after drying, break down to mud when wetted with water or oils. Slaking is a very undesirable quality in granular fuller's earth products because it decreases odor control and increases liquid buildup in cat litter and causes unsafe slippery conditions when used as a floor-sweep compound type of oil absorbent product. Slaking is caused by dispersion of the surface of the clay granules to form a slick surface, in which the clay crystallites are uniformly negatively charged and consequently repel each other. Paradoxically, although slaking is undesirable behavior in granular fuller's earth products, it is essential in gelling clays.

Quality Testing

Companies that produce fuller's earth test their exploratory drill core and quality control samples against a variety of published and unpublished product specifications that are important to their customers. Fuller's earth product specifications are set by the type of market use intended. The initial critical quality factor is the percentage of coarse inert impurity materials, commonly termed *grit*, that contaminate the clay deposit. Grit specifications for the maximum allowable nonabsorptive minerals present in crude clays can range from 5% to as much as 15%. Some of the coarser grit material can be partly removed by air separation at the whizzer during dry milling or by oversize screening when producing granular products.

Dry calcined MgO can be added to the raw clay during processing to improve gelling, viscosity, and thickening behavior. It may be necessary to extrude the moist clay for crystallite alignment or to allow for a seasoning time of up to 2 weeks to allow the MgO to have its maximum desired effect.

Granular fuller's earth products commonly must be composed of a narrow size range of chip particles, with very little fine dust-size material allowed. Dusting behavior can be a problem with many of the softer or more frangible absorbent fuller's earth products. When dried or semicalcined and then crushed to a granular or chip-sized product, the finer mesh sizes of clay may need to be removed and discarded to meet the customer's particle-size specifications. De-dusting boxes and liquid polytetrafluoroethylene addition may be used to reduce airborne dust immediately before packaging. Slaking is also a quality problem, where the clay granules break down when wetted and form an impermeable, nonabsorbent muddy mass.

The American Petroleum Institute (Anon. 1969) lists drilling mud specifications. Specification P-A-1056A, published by the U.S. General Services Administration, describes tests for floor-sweep-type absorbent granules. The American Oil Chemists' Society

(Anon. 1958) describes edible oil bleaching tests. Weidhaus and Brann (1955) describe testing for the various types of insecticide, carrier, and dusting diluents.

Product Performance Standards

The following are general guidelines for specific fuller's earth products intended for particular market applications.

Granular products intended for cat litter should be light in color with a loose packaged density of less than 50 lb/ft³, and when crushed they should produce a minimum of fine dust-size material. Low bulk density is especially important for high-quality consumer cat litter; the purchaser will select generous-size packages that weigh as little as possible.

The same low bulk density, however, will increase per-ton shipping cost in railcars and export containers. Litter granule size usually ranges from about 4 to 30 Tyler screen mesh, and liquid absorptivity ranges from 50% to 120% without slaking or granule breakdown. Cat litter products are typically dried to 10% to 15% moisture, and western bentonite is commonly added to absorb liquid waste into easily removed, scoopable clumps.

Granular oil-absorbent fuller's earth products vary in density from 22 to 52 lb/ft³, with non-slaking oil absorption ranging from 50% to 100%. Hard granules, low dusting, and high adsorption ability all bring a premium price for this type of product, which is generally sold at 0% moisture.

Agricultural granules for use as carrier agents for liquid insecticides, herbicides, bactericides, nutrients, and fungicides are generally sold in screen sizes ranging from 24 to 48, or 30 to 60 Tyler mesh, with minimal dusting or slaking allowed. These products are commonly produced from Porters Creek Clay in the midcontinent Mississippi Embayment area and are dried to 0% moisture.

Gelling-type fuller's earth products are tested by measurement of slurry viscosity at low clay solids percentages. The most widely used viscometers are the low shear Brookfield unit at 100 rpm or the high shear Fann unit at 600 rpm, depending on customer preference and market application. Clay slurry viscosity can be tested with either fresh or supersaturated saline water.

Magnesium-rich attapulgite fuller's earth clays retain good gel strength under saline conditions, whereas sodium- or calcium-based montmorillonite gelling products break down in the presence of salt water. Therefore, attapulgite fuller's earth is selected as a high-gelling drilling mud for oil and gas exploration when expecting saline formation conditions. For such drilling use, a 600-rpm clay testing 30 Fann units will equate to 100-bbl yield units of properly thickened mud per ton.

Bleaching fuller's earth clays are used to purify and remove discoloring agents from edible oils and liquid products. These products must have very specific pore sizes and shapes to absorb impurities properly while allowing the clarified liquid to filter easily through the clay. The only U.S. fuller's earth products suitable for this use are produced in the Jackson Area of Mississippi and the Meigs to Ochlocknee mining districts of Georgia. These specialty clays are dried to no less than 10% moisture, ground to finer than 325 mesh, and acid treated or soaked for enhanced activation.

Fuller's earth used for sports turf or lawn growth aids (for athletic playing fields or golf courses) is usually dried hard at high temperature to light red, making granular products similar in size to cat litter. These products loosen soils for better drainage and more effective use of plant nutrients.

MINING

Fuller's earth is mined by open-pit methods (Figure 2). Generally, mine planning and permitting, followed by overburden excavation,

are based on core drilling on grids of 50 to 100 ft and careful clay quality testing. Overburden is, whenever possible, backfilled into nearby previously mined-out pits and sloped to blend in with the original, premining terrain. After the overburden is removed, closer spaced drilling using compressed air or auger sample return is frequently done on 50 to 25 ft spacing for effective mine quality control.

Overburden is stripped with backhoe excavators and off-road haul trucks, or dozers and scrapers, often by local independent contractors (Figure 3). The clay itself is excavated with backhoes, front-end loaders, or scrapers. Because the sedimentary fuller's earth was deposited in horizontal layers or strata, quality control is much more reliable if the clay is mixed during mining by vertical excavation (such as with hydraulic backhoes). This vertical mining averages out the horizontal layering of quality variations and delivers better-blended crude clay to the stockpile or processing plant. Acceptable overburden thickness can range from only a few feet or meters to more than 100 ft, depending on the mining district, ore zone thickness, clay quality, and the market value of products produced.

Highway haul trucks transport the crude clay from the property; they must meet complex state and interstate regulations for haul weight, individual wheel load bearing, spillage, tracking mud onto the paved road surface, and so forth. Thus, there is a real cost and efficiency advantage to mining near enough to the clay processing plant so that mine-run crude clay can be hauled by very large off-road trucks on privately owned roads, where regulated load limits do not apply. After a fuller's earth plant has operated for a few decades, however, it is likely that most or all of the nearby acceptable quality clay deposits have already been mined out.

Mine Permitting and Regulation

Proposed fuller's earth mines must be approved and permitted by state and local agencies. Each mine permit process addresses reclamation, air quality, stormwater runoff, local zoning, and other regulatory issues. The permit process can be very different from state to state, and may vary considerably through time in an individual state. Careful attention should also be paid to wetlands, county zoning regulations, Native American tribal customs and practices, proximity to historic homes or buildings, parks, natural areas, wildlife sanctuaries, or endangered species regulations.

Mine permitting must also deal with land and mineral ownership and leasehold rights, mine water control, highwall slope stability (typically laid back to between 0.5:1 and 2:1 angles), adjacent property setback, and so forth. Mineral rights on privately owned lands are commonly leased from the landowners, and royalties for extracted clay are paid by the ton or cubic yard.

Failing to obtain a satisfactory lease contract, mining companies may purchase clay properties outright or buy the deeded, severed minerals only and leave surface and timber ownership to the landowner. On federal lands, the U.S. Bureau of Land Management or the U.S. Bureau of Indian Affairs must handle mineral leasing or placer claims in accordance with the General Mining Act of 1872 and their own particular standards and regulations.

Mined Land Reclamation

Once mining is completed, the mined-out pits are backfilled and leveled with overburden from a nearby or adjacent cut, or developed into fishing ponds. The disturbed land is restored to attractive, stable, noneroding, less than 3:1 slopes. Cover crops of pasture grass and select tree seedlings are planted on the reclaimed land to leave little or no hint that the property had ever been mined. Individual states, and in some cases also a county or smaller local permitting agency, control regulation of such privately owned disturbed mining lands in the United States.

Figure 2. Typical open pit fuller's earth mine near Ochlocknee, Georgia, showing the excavated surface of the minable clay under approximately 20 m of overburden. Ore zone thickness is approximately 4 m.

Figure 3. Mining fuller's earth clay after overburden has been removed and hauling by highway truck to the processing plant. Note overburden in the background that has been backfilled to fill the previously mined-out pit.

CLAY PRODUCT PROCESSING

Fuller's earth is an unusually versatile mineral that can be processed to meet a rather bewildering variety of product specifications for sales to a wide range of differing market uses. Crude run-of-mine fuller's earth is typically crushed and semidried with a shredder or hammer mill, Raymond mill, Williams mill, or Imp mill for bleaching and gelling products.

The clay may be dried to 10% to 15% moisture or semicalcined. Care is taken not to overheat and reduce pore size, absorption, or CEC, and alter mineralogy to make cat litter, bleaching and oil-adsorbent material, agricultural chemical carriers (for pesticides, herbicides, etc.), jet fuel filtration agents, or turf improvement products.

Various-sized granular products can be screened to make any product from 4 by 12 mesh, 30 by 60 mesh, or even as fine as 60 to 90 Tyler mesh specifications. Finer clay products can be ground

and air-float separated to finer than 200 mesh, 325 mesh, or even ultrafine –6- μ m material. The moist clay can be “pugged” (extruded) to align elongate crystals and improve gelling properties.

MgO may be added to improve product viscosity and gelling characteristics. There is not agreement in the industry on whether adding MgO causes actual attapulgite crystal needle growth after a few days’ residence in the clay product, or if the MgO simply results in an improved surface charge on the existing clay crystal-lites that results in better gel performance.

PRODUCT HEALTH AND SAFETY CONSIDERATIONS

Crude fuller’s earth clay is checked by scanning electron microscope, transmission electron microscope, x-ray diffraction, and x-ray fluorescence chemical analysis for the presence of industrial fibers of possible asbestiform characteristics, cristobalite, trace metals, and other possible hazardous elements. Because some fuller’s earth products may be used for processing animal and human foods, all products and additives used must meet food-grade standards. Several examples of possible hazardous situations that have affected fuller’s earth operations are as follows:

- Development of East Gate, Nevada, mordenite for cat litter use was halted because of the presence of erionite fibers in the crude clay and overburden.
